Embedded Meetings & Industry Days

AMU, Talks

AM/DEM4049/005: **Applied mathematics relevant to Africa.**

Organiser: Jan Persens (University of the Western Cape, South Africa)
Co-organiser: Abderrahman Boukricha (Universite de Tunis El Manar, Tunisia)

In this embedded meeting applied mathematics problems will be presented and tackled which are relevant to Africa. Examples will be the modeling of the spreading of deseases, modelisation of the immune system for responding to malaria parasite plasmodium falcuparum, age-structured epidemic models with vertical transmission and vaccination, mathematical problems related to ecology.

Missing boundary-data recovery and applications. **Amel Ben Abda** (Ecole Nationale d'Ingenieurs de Tunis, Tunisia) AM/TEM4053/005

We consider in this work the problem of recovering missing data on some part of the boundary of a domain from over-specified boundary data on the remaining part of the boundary. This kind of problem occurs often in the engineering sciences, as the reconstruction of physical variables from lacking data is highly useful in many industrial processes. A more common problem, occurring in thermostatics, consists of recovering the temperature in a given domain when the distribution of it and of the heat flux along the accessible region of the boundary are known. Given a flux Φ and the corresponding temperature T on Γ_c, one wants to recover the corresponding flux and temperature on the remaining part of the boundary Γ_i, where Γ_c and Γ_i constitute a partition of the whole boundary $\partial\Omega$. The problem is therefore set as follows:

Find (φ, t) on Γ_i such that there exists a temperature field u satisfying:

$$\nabla \cdot k(x)\nabla u = 0 \text{ in } \Omega, \quad k(x)\nabla u \cdot n = \Phi \text{ on } \Gamma_c, \quad u = T \text{ on } \Gamma_c,$$

where the conductibility field $k(x)$ is real analytic in $L^\infty(\Omega)$. This problem has been known since Hadamard to be ill-posed, in the sense that the dependence of u and consequently of (φ, t) on the data (Φ, T) is known to be not continuous. Two approaches are presented to reconstruct the missing data (φ, t): The first one builds an energy like error functional, the second one resorts to Domain Decomposition tools. These two methods have been successfully numerically experimented for the Laplacian operator.

Applications to the inverse ElectoCardioGraphy (ECG) and ElectroEncephaloGraphy (EEG) probems will be presented.

Population dynamics and epidemic diseases models. **Mohamed El-Doma** (University of Khartoum, Sudan) AM/TEM4070/005

In this talk, we will introduce population models as well as epidemic diseases models. In general there are two main types of models, namely, deterministic models and stochastic models. We only present deterministic models, and concentrate our efforts on structured population models. In particular, we consider populations that are structured either by age, where age is assumed to be the chronological age, that is, the time since birth, or size.

For epidemic diseases models, we concentrate our efforts in age-structured population models where diseases can be transmitted vertically or horizontally or by both modes of transmission, for example, diseases like AIDS, chagas, gonorrhea and hepatitis B are vertically as well as horizontally transmitted, whereas diseases like malaria and tuberculosis are horizontally transmitted. We also consider situations where diseases can cause significant fatalities. It is worth mentioning that such models are seldom considered in the literature, this is partly due to the added mathematical difficulties that arise in such situation. In addition, we introduce vaccination for epidemic diseases models and obtain some conclusions about their eradication.

For size-structured population models, we give some stability results, for the finite size case, which may corresponds to harvesting at specific size, and for the infinite size case.

Modelling the cellular-level interaction between the immune system and viruses. **Gareth Witten** (University of Cape Town, South Africa) AM/TEM4131/005

Mathematical models have shown to provide substantial insights into our understanding of the dynamics of viruses, in particular, the human immunodefiency virus, at both the population and cellular level. Collaboration between experimentalists and mathematical modellers have allowed models to be evaluated and parameterised, and used to test several key hypotheses, for example, the role of the immune system in the progression of the disease and how HIV evolves resistance to antiretroviral treatment. An explosion of the application of mathematical models at the cellular level was seen in the 1980Šs and thus far success in describing HIV and other viruses has been due, in part, to the availability of reliable experimental data. However, there remains a number of puzzling quantitative features. In this presentation I will review the major biological questions being asked and attempt to sketch the development of the mathematical models in this area and how these models have impacted our understanding of HIV pathogenesis in southern Africa.

CSIAM, Talks

CS/DEM4121/015: Industrial and applied mathematics in China.

Organiser: Ya-xiang Yuan (Chinese Academy of Sciences)
Co-organiser: Tatsien Li (Fudan University, PR China)

Inverse heat-transfer problems in steel industry. **Yongji Tan** (Fudan University, PR China) CS/TEM4310/159

In this paper, two problems from the steel industry are discussed. The first one is the control problem for the secondary cooling of continuous casting. The second concerns monitoring the corrosion of the inner wall of the blast furnace and steel ladle. Both problems are formulated as inverse heat-transfer problems and solved by suitable numerical methods. Some theoretic results related to the corrosion problem are obtained.

The generating function of a pricing mechanism for financial derivatives. **Freddy Delbaen** (ETH Zürich, Switzerland), Shige Peng (Shandong Universiity, PR China) CS/TEM4568/159

In this talk we present a theoretical and market-data test of dynamic pricing mechanisms for financial derivatives. A typical model of such a pricing mechanism is the so-called g-expectation defined by solutions of a backward stochastic differential equation with g as its generating function. The Black-Scholes pricing model is a special linear case of this pricing mechanism. We are mainly concerned with two types of pricing mechanisms in an option market: the market pricing mechanism through which the market prices of options are produced; and the ask-bid pricing mechanism operated through the system of market makers. The later one is a typical nonlinear pricing mechanism. Data of prices produced by these two pricing mechanisms are usually quoted in an option market.

We introduce a criteria (i.e., the domination condition) to test whether a dynamic pricing mechanism under investigation is a g-pricing mechanism. This domination condition was statistically tested using CME data documents. The result of the test is significantly positive. We also provide some useful characterizations of a pricing mechanism by its generating function.

Recent existence results for the multidimensional compressible Navier–Stokes equations. **Song Jiang** (IAPCM, Beijing, PR China) CS/TEM4257/159

Modelling, analysis and numerical simulations are the important aspects in applied mathematics. In this talk we shall concentrate on the analysis aspect of the multidimensional compressible Navier-Stokes equations, which describe the motion of compressible viscous fluids and are a nonlinear hyperbolic-parabolic coupled system. In the last decades significant progress has been made on the mathematical aspect of the Navier-Stokes equations for multidimensional compressible flow. We shall briefly review some recent global existence results on the Cauchy problem with large data. The ideas and developed techniques used in obtaining the global well-posedness will be presented, and some open questions will be discussed.

CS/DEM4121/015: Industrial and applied mathematics in China. #2

Organiser: Ya-xiang Yuan (Chinese Academy of Sciences)
Co-organiser: Tatsien Li (Fudan University, PR China)

(For abstract, see session #1 above.)

Solving a class of constrained black-box inverse variational inequalities. **Bingsheng He** (Nanjing University, PR China) CS/TEM5067/159

Development of computerized tomography in China. **Peng Zhang** (Capital Normal University, PR China) CS/TEM4283/159

X-ray computed tomography (CT) is a one of the great technological achievements in the last century and is critically important for life science, patient care and non-destructive testing in industry, etc. In this rapidly developing field, applied mathematics is a most powerful tool for development of image reconstruction and image processing theory and methods. This talk is a survey of the work on computerized tomography and its applications conducted by Chinese applied mathematicians in the last two decades. It consists of five parts. Part 1 is an overview of the history and development of the research on computerized tomography in China. Part 2 is an introduction of CT theory, scanning configurations, and image reconstruction algorithms. Part 3 is a report on recent achievements by Chinese groups on typical issues in industrial nondestructive testing, including ROI (region of interesting) reconstruction, reconstruction from limited angle data, multiple scanning configurations for large view of field, super-resolution reconstruction, fast implementation of CT reconstruction algorithms, 3D visualization of huge CT data, and virtual design of industrial CT systems, etc. Part 4 are representative applications in medical imaging, material science, nondestructive industrial testing and fossil imaging. Part 5 is a perspective of emerging tomography techniques such as phase-contrast tomography and bioluminescence tomography and future research opportunities. This talk ends with a discussion on the policy for promoting applied and industrial mathematics in China. The presentation is based on the work of collaborators and images kindly provided by other groups in China.

Dynamical modeling based on energy dissipation. **Pingwen Zhang** (Peking University, PR China) CS/TEM4256/159

Energy dissipation for a dynamical model is important not only for the physical correctness but also for stable and robust numerical simulation. In this talk, we introduce a systemic technique for dynamical modeling and a way from energy dissipation law to dynamical equations. We will present a new closure approximation needed for deriving effective macroscopic moment equations from the microscopic FENE kinetic theory modeling viscoelastic polymeric fluids and inhomogeneous kinetic theory of liquid crystal polymers. The simplified system coupling the moment equations and the Navier-Stokes equations still possesses an approximated energy law analogous to the original micro-macro system. Some other examples for complicated coupled models of polymer phase separation and dynamical cell membrane are introduced to expound the whole process. Numerical results show good stability of these models as well as the numerical schemes.

ESMTB Plenary Lecture

ES/IT4124: *Models for cell motility by filament-elongation motors*
Richard Dickinson (University of Florida, USA)

Filament end-tracking proteins, which bind onto and processively advance with elongating cytoskeletal filament ends, play a fundamental and perhaps ubiquitous role in force generation during polymerization of actin filaments and microtubules. These filament end-tracking motors capture energy from nucleoside triphosphate (ATP or GTP) hydrolysis at the filament ends for elongation and force generation by modulating the affinity between end-tracking proteins and filament subunits in a manner that facilitates processive monomer addition and filament end-tracking. Mechanochemical models of force-dependent filament elongation kinetics together with reaction–diffusion–mechanical models of motility demonstrate that the existence of end-tracking motors operating on actin filaments plus-ends can quantitatively explain key observations in various recent studies of actin-based propulsion of particles coated with nucleaction promoting factors (ActA, VASP, N-WASP), such as particle speed, deformations, and saltatory motion.

This work was done in collaboration with Daniel L. Purich, Dept. of Biochemistry and Molecular Biology, University of Florida College of Medicine.

ES/IT3378: *Stochastic modelling of interacting biological populations*
Vincenzo Capasso (Università degli Studi di Milano, Italy)

Particular attention is being paid these days to the mathematical modelling of the social behaviour of individuals in a biological population, for different reasons; on one hand there is an intrinsic interest in population dynamics of swarms, on the other hand agent based models are being used in complex optimization problems (ACOs; i.e. Ant Colony Optimization). Further decentralized/parallel computing is exploiting the capabilities of discretization of nonlinear reaction–diffusion systems by means of stochastic interacting particle systems.

Among other interesting features, these systems lead to selforganization phenomena, which exhibit interesting spatial patterns. Current interest concerns how do properties on the macroscopic level depend on interactions at the microscopic level. Among the scopes of the lecture, a relevant one is to show how to bridge different scales at which biological processes evolve; in particular suitable *laws of large numbers* are shown to imply convergence of the evolution equations for empirical spatial distributions of interacting individuals to nonlinear reaction–diffusion equations for a so called mean field, as the total number of individuals becomes sufficiently large.

In order to support a rigorous derivation of the asymptotic nonlinear integrodifferential equation,problems of existence of a weak/entropic solution will be analyzed. Further the existence of a nontrivial invariant probability measure is analyzed for the stochastic system of interacting particles.

This is work performed in collaboration with M. Burger, D. Morale.

ES/IT3766: *Cell interactions under flow: experiments and modelling*
Claude Verdier (CNRS & Université Grenoble I, France)

We describe the mechanisms which rule the different laws governing cell–cell interactions, in particular when leukocytes or cancer cells interact with the endothelium under flow conditions. These mechanisms can lead to cell rolling and extravasation. Important issues concern cellular adhesion, cell microrheology, the influence of shear stresses, and mechanotransduction.

Experiments are performed to understand these features using microrheology techniques[1], as well as flow chambers to investigate cell–cell interactions. Different behaviors are exhibited[2], in which cancer cells show totally different behaviors; they either intermingle within the endothelium and form mosaic monolayers, or disappear at cell–cell junctions (i.e., extravasation).

Different processes such as kinetic models or stochastic ones can be used to include the adhesion effects. Biochemical bonds can be formed or broken in a probabilistic way or through kinetic reactions. This is included in a 3D model of a cell interacting with a rigid wall[3]. The cell is considered as a viscoelastic composite object surrounded with a membrane with cortical tension. Simulations have been compared with experiments involving the rolling of leukocytes on the endothelium.

ESMTB, Talks

ES/DEM4883/000: **Cell dynamics and ECM interactions.**
Organiser: Luigi Preziosi (Politecnico di Torino, Italy)
Co-organiser: Wolfgang Alt (Universität Bonn, Germany)
Co-organiser: Andreas Deutsch (TU Dresden, Germany)

Cellular traction as an inverse problem. **Davide Ambrosi** (Politecnico di Torino, Italy) ES/TEM3323/120

The evaluation of the traction exerted by a cell on a planar substrate is here considered as an inverse problem: shear stress is calculated on the basis of the measurement of the deformation of the underlying gel layer. The adjoint problem of the direct two-dimensional plain stress operator is derived by a suitable minimization requirement. The resulting coupled systems of elliptic partial differential equations (the direct and the adjoint problem) are solved by a finite element method and tested vs. experimental measures of displacement induced by a fibroblast cell traction.

Continuum model of cell adhesion and migration. **Esa Kuusela** (Universität Bonn, Germany), Wolfgang Alt (Universität Bonn, Germany) ES/TEM4152/120

Certain types of cells (e.g., *keratinocytes*), have the ability to move on surfaces with appropriate adhesive coating. Modeling the complicated intra-cellular processes generating this motion forms an intriguing challenge to the mathematical biologists. The essential cell functions for motion are at least the continuous polymerization, depolymerization and deformation of intra-cellular actin filament network, as well as the evolution of cell membrane protein structures that can mediate the network generated forces to the underlying surface.

We will here describe a large-scale continuum model capable of treating these microscopic processes. The 2-dimensional model consists of two layers. The top layer describes the interior of the cell as a two-phase fluid where the components are the highly viscous dynamic filament network and the low viscous intra-cellular liquid, the cytosol. The bottom layer consist of the cell membrane and the discrete focal adhesion cites.

The presented model realistically handles the polymerization, depolymerization and flow of filament network in whole cells and cell fragments. We will also show that this simple model is able to show many of the characteristics of moving keratinocytes like rapid protrusion and retrograde flow of actin filaments.

A comparison of chemotaxis *models.* **Thomas Hillen** (University of Alberta, Canada) ES/TEM3401/120

Macroscopic models for chemotaxis are partial differential equations with cross diffusion and are of Keller-Segel type. Various versions of the Keller-Segel model have been used in the literature for various purposes. In this talk I will review and compare different subclasses which I roughly classify into eight categories: 1. classical, 2. receptor binding, 3. volume filling, 4. saturation in the chemotactic sensitivity, 5. non-local gradient sensing, 6. nonlinear diffusion, 7. saturation in the chemical signal, and 8. population kinetics.

For each of these model classes I will present applications, review results on local and global existence, and discuss pattern formation. It turns out that coarsening of pattern is a common property of all these models. We demonstrate this numerically (joint work with K. Painter, Edinburgh).

ES/DEM4884/000: Dynamics of cell populations.

Organiser: Wolfgang Alt (Universität Bonn, Germany)
Co-organiser: Luigi Preziosi (Politecnico di Torino, Italy)
Co-organiser: Andreas Deutsch (TU Dresden, Germany)

Cellular automaton modelling of spatio-temporal pattern formation in interacting cell systems. **Andreas Deutsch** (TU Dresden, Germany) ES/TEM4329/120

Examples of spatio-temporal pattern formation are life cycles of bacteria and social amoebae, embryonic tissue formation, wound healing or tumour growth. Thereby, development of a particular spatio-temporal "multi-cellular" pattern may be interpreted as cooperative phenomenon emerging from an intricate interplay of local (e.g. by adhesion) and non-local (e.g. via diffusing signals) cell interactions. What are cooperative phenomena in interacting cell systems and how can they be studied?

Mathematical models are required for the analysis of cooperative phenomena. Typical modeling attempts focus on a macroscopic perspective, i.e. the models (e.g. partial differential equations) describe the spatio-temporal dynamics of cell concentrations. More recently, cell-based models have been suggested in which the fate of each individual cell can be tracked. Cellular automata are discrete dynamical systems and may be utilized as cell-based models.

Here, we analyze spatio-temporal pattern formation in cellular automaton models of interacting discrete cells. We introduce lattice-gas cellular automata and a cellular automaton based on an extended Potts model that allows to consider cell shapes. Model applications are bacterial pattern formation and tumour growth.

From single cells to tissue architecture: a bottom-up approach to modelling the spatio-temporal organisation of complex multicellular systems. **Joerg Galle** (Universität Leipzig, Germany), Dirk Drasdo (University of Warwick, UK) ES/TEM4133/120

Collective phenomena in multi-cellular assemblies can be approached on different levels of complexity. Here, we review a number of mathematical models which consider the dynamics of each individual cell; so called individual cell-based models (IBMs). As a special feature, these models allow to account for intracellular decision processes, triggered e.g. by biomechanical cell-cell or cell-matrix interactions. Consequently, they allow studying the impact of regulatory malfunction on the growth and homeostasis of the assembly under consideration. This is achieved assuming that the intracellular processes act on a limited number of effective cell-biological and biophysical parameters. In the case that these parameters are experimentally accessible, IBMs can reach a stage where they may contribute to unveil the processes that underlie the organization of tissues and multicellular aggregates. The applications discussed here range from regulation of growth and contraction of in vitro cell populations to cell-contact dependent regulation of tumor morphology.

Periodic hematological disease: insight into origins derived from mathematical modeling. **Michael Mackey** (McGill University, Canada) ES/TEM3329/120

There are a variety of periodic hematological diseases such as cyclical neutropenia, cyclical thrombocytopenia, and periodic leukemia. Each presents their own difficulties to the mathematical modeler in terms of trying to deduce the possible origins of the abnormal dynamics and suggesting treatment methods. This talk will focus on these issues using selected diseases as case studies.

ES/DEM1219/010: Subcellular dynamics.

Organiser: Andreas Deutsch (TU Dresden, Germany)
Co-organiser: Luigi Preziosi (Politecnico di Torino, Italy)
Co-organiser: Wolfgang Alt (Universität Bonn, Germany)

The purpose of the European Society for Mathematical and Theoretical Biology is to promote the development of theoretical approaches and mathematical tools in biology and medicine which has an undisputable medical, industrial and social interests.

Insights and predictions from mathematical modelling are used increasingly in decision support in medicine (e.g. immunology and spread of infectious diseases, cancer research, cardio-vascular research, neurological research, optimisation of medical treatments, imaging). The research trend is now to look at the phenomena occurring at the cellular and subcellular scales, e.g., cell motion and behaviour, signal transduction, genomics, proteomics.

In this respect this embedded meeting has as its goal to foster interdisciplinary collaboration between mathematicians and bioscientists and to act as a forum for the presentation of recent research results and new research directions in computational cell biology.

Systems biology towards life in silico*: mathematics of the control and regulation of living cells.* **Hans Westerhoff** (Vrije Universiteit Amsterdam, The Netherlands) ES/TEM5037/120

Systems Biology is the science that discovers general principles underlying the emergence of biological function from the interactions of components of living systems. By specifying in a <91>silicon cell<92> the dynamic ways in which macromolecules interact, the emergent properties can be calculated through numerical mathematics. This approach is on its way towards the calculation of more and more of living organisms in the computer. These silicon cells help discover new principles of Life by induction, providing a new route, parallel to empirical Biology, and similar to computational physics. They also enable differential network-based drug design.

Much of Biology progresses as an empirical science where discoveries are made by experimental testing of hypotheses. By abstracting the ways macromolecules <91>listen<92> and <91>talk<92> to each other in living cells, a set of elemental properties can be formulated for living organisms. These then enable the deduction through mathematics of principles that are important for control and regulation of the vital fluxes of living cells. The simplest of these will be illustrated, for the control, regulation and robustness of fluxes, of oscillations and of signal transduction relevant for cancer.

Modelling asymmetric division in the early C. elegans *embryo.* **François Nédélec** (EMBL, Heidelberg, Germany) ES/TEM4272/120

Interactions between microtubules fibers and the cell cortex play a critical role in positioning organelles in a variety of biological contexts. In *C. elegans*, for example, cortical forces acting on microtubules originating from the spindle-poles displace the mitotic spindle towards the posterior in response to polarity-cues. Using EBP::GFP and YFP::tubulin we observed that microtubules shrink soon after touching the cortex. From this, we proposed that cortical adaptors mediate microtubule depolymerization energy into pulling forces. We then used stochastic computer simulations to show that such force production mechanism is crucially determined by the assembly/disassembly dynamics of fibers and their mechanical properties. Furthermore, we show that these simulations reproduce faithfully anaphase spindle oscillations and posterior displacement in 3D.

Automated analysis of spatio-temporal cell microscopy images: classification, tracking, and registration. **Karl Rohr** (Universität Heidelberg, Germany), Nathalie Harder (Universität Heidelberg, Germany), Roland Eils (Universität Heidelberg, Germany) ES/TEM4835/120

The effectiveness of large-scale and high-content cellular screening techniques in biological applications significantly depends on the analysis of the acquired image data. Because of the enormous increase in the generation of 2D, 3D, and 4D microscopy images a manual evaluation is no longer possible and a computer-based analysis is necessary.

We have developed an image analysis approach for the evaluation of large-scale cell phenotype screens generated by high-throughput RNAi experiments. Based on confocal fluorescence microscopy cell-array images the task is to determine the influence of genes on the process of cell division and thus to identify gene function. Our approach allows to automatically segment and classify cell nuclei into different cellular phenotypes. The segmentation of cells is based on an efficient region-adaptive thresholding scheme. For cell classification we employ support vector machines using a large spectrum of image features. We have also developed a tracking scheme which exploits the temporal information in consecutive time-lapse images and thus enables to compute the ancestral relationships between cells.

Another central task in biological image analysis is the normalization of cell microscopy images for subsequent quantification and statistical analysis of the cell structure. To this end a geometric transformation needs to be computed. The task of finding an optimal geometric transformation between corresponding image data is known as image registration and generally one has to use non-rigid (elastic) deformation models. We have developed elastic registration approaches for image normalization and have successfully applied them to multi-channel confocal cell nucleus images.

Aircraft Design, Talks

AD/DID430/061: **Numerical optimization for industrial aircraft design.**

Organiser: Nicolas Gauger (HU Berlin & DLR Braunschweig, Germany)
Co-organiser: Norbert Kroll (DLR Braunschweig, Germany)
Co-organiser: Klaus Becker (Airbus Deutschland GmbH, Germany)

The workshop is organized by the Pilot Center Germany North of ERCOFTAC and aims to bring together research scientists from universities, research institutes and industry that work in the field of aerodynamic shape optimization. The requirements for practical shape optimization will be worked out, new solution approaches and optimization tools from research institutes will be presented in conjunction with innovative ideas from the forefront of mathematical research at universities. Particular attention will be paid to the fact that aerodynamic shape optimization is a part of a larger, multi-disciplinary design process.

Numerical optimization for industrial aircraft design at Airbus. **Murray Cross** (Airbus, UK) AD/TID4524/061

There is an ever increasing requirement to improve the performance and cost effectiveness of commercial aircraft due in a competitive marketplace with multiple external constraints. Looking back at history we see tremendous strides in efficiency and effectiveness of such commercial aircraft, enabled by improving technology, tools, processes and knowledge. This optimisation process is a fundamental part of an aerospace engineers approach, and part of the natural ability to look at different approaches and selecting the best technique for applying to the job in hand. In recent times and certainly in the future, a combination of the complexity of the engineering system, the requirement to attain higher and higher levels of performance, and the increased technical capability, has lead to the introduction of numerical optimisation techniques coupled with high fidelity engineering analysis.

This presentation will review the need for optimisation, the key technologies enabling such techniques, and applications for such techniques in an Airbus Engineering context, with a focus on aerodynamics.

Status and challenges of aeroshape design of future aircrafts. **Phillipe Rostand** (Dassault Aviation, France) AD/TID4525/061

Aeroshape design of aircrafts is a continuously evolving process; very significant progresses have been made in the last ten years and a high degree of maturity has been reached. Most of the elements of the arodynamics of conventional fighter aircrafts or business jets are modeled and understood to a degree, and so can be the object of reasonably deterministic design processes. Consequently innovative designs have been obtained which could not have been derived earlier, and large efficiency gains in the design process have been observed. Progresses have been obtained combining research efforts of industry, research centers and academia; a summary of recent results for business jet design is presented. However new challenges have appeared that call for further evolution of processes, on which current research efforts are focused. New challenges come primarily from: New environmental requirements, which call for significant changes in business jet design, with community noise reduction a first level objective if ACARE targets are to be met, Stealth requirements, to be fully integrated in combat manned and unmanned aircraft design processes. New competitivity requirements, both on performances, in particular on aircraft speed, with the Supersonic Business Jet, and on recurring and non-recurring costs, Risk reduction requirements, in particular in the much shortened design phases.

Experiences in aerodynamic shape optimization at EADS-military aircraft systems. **Herbert Rieger** (EADS Military Air Systems, Germany), Norbert Kroll (DLR Braunschweig, Germany), Klaus Becker (Airbus Deutschland GmbH, Germany) AD/TID4526/061

In recent years the numerical aerodynamic simulation methodology has demonstrated the enormous potential by which that technology can contribute to improvements of aircraft design during almost all stages of aircraft development. This has fostered the use of advanced optimization techniques for complex aerodynamic shape design which involves also multidisciplinary considerations. Presently the aerospace industry has the choice over a wide range of different optimization algorithms which rely e.g. on gradient-based, evolutionary and genetic optimization algorithms. The approach taken is to identify for the specific problem at hand the best suited optimization technique offered in a general multiobjective design optimization environment which allows easily organizing and adapting the necessary work flow. Over the years EADS Military Aircraft Systems has developed, implemented and automated all process elements to build up an advanced design and optimization capability based on a parametric CAD geometry modeling approach for providing the geometry models suitable for an automated unstructured mesh generation system as well as a flexible flow simulation system which handles all kind of steady or unsteady RANS flow problems with and without moving boundaries. The results of the approach on various optimization problems are presented ranging from simpler 2D aerodynamic problems up the multi-point and multi-objective optimization of full aircraft configurations as a multi-disciplinary approach including structural considerations and requirements.

Novel techniques for aerodynamic design optimization. **Volker Schulz** (Universität Trier, Germany) AD/TID4527/061

Aerodynamic design is an engineering issue of high economic importance. Often, tedious experimental as well as numerical studies are involved. In a collborative effort of DLR Braunschweig and University of Trier, new mathematical tools have been developed, which can speed up the design process enormously from a computational point of view. The talk will discuss the theoretical and the practical asepcts of these techniques which are based on one-shot methods.The robust treatment of model unsecurities pose additional challenges and will play a role, too.

Theory and practice of optimal shape design for fluids. **Bijan Mohammadi** (Université Montpellier II, France), Olivier Pironneau (Université Paris VI, France) AD/TID4528/061

This is a survey of some recent developments in Optimal Shape Design (OSD) for fluids. Existence, sensitivity, compatibility of discretizations as well as efficient algorithmic implementations with low complexity are critical. We discuss some of these issues with application to shape optimization for aerodynamic noise reduction in supersonic (sonic boom) and subsonic regimes (noise due to aerodynamic unsteadinesses).

Coupling of sizing optimization and topology optimization for industrial aircraft design. **Joachim Gwinner** (Universität der Bundeswehr München, Germany) AD/TID4529/061

In structural aircraft design as well as in other applications of light weight design it is important to optimize simultaneously all load bearing members of a structure, like skin, stringer, longerons and frames,

in one optimization loop. Very often, sizing optimization with respect to member size or thickness has been separately applied to the single low dimensional members; e.g., to the skin modelled by shell elements or the longereons, modelled by beam elements, respectively. On the other side, stand alone topology optimization with respect to the density as design variable has been applied to single frames to find the relevant load paths and an optimal material distribution. Clearly, a direct numerical treatment of the total structure based on a complete FE discretization leads to large (although sparse) linear systems that have to be called for and solved by Gauss-Cholesky factorization within the optimization loop and is thus prohibitive in view of a plentitude of different loading cases and failure modes.

In contrast, during the last decade, iterative domain decomposition methods have become a major tool in numerical analysis of partial differential equations. Such methods kave been more recently[1,3] invented and studied in the foreward analysis of coupled ODE-PDEs. Moreover domain decomposition methods have also been developped for the optimal control of PDEs on multi-linked or networked domains[4]. Finally at the infinite-dimension level, structural optimization, in particular topolgy optimization can be seen[2] as a problem of control in the coefficients.

It is obvious from the physical point of view that such decompositions should respect the structural members as individuals coupled at multiple joints. Thus we seek the decoupling of multiple joint conditions or, put in other words, a nonoverlapping domain decomposition procedure, what in engineering terminology can be labelled as a substructuring approach. Here in this contribution we concentrate to coupled 1D/2D structures (beam/plane linear elasticity) and develop iterative domain decomposition methods in structural optimization.

Electromagnetics, Talks

EL/DID1032/015: Challenges in computational electromagnetics.

Organiser: Ralf Hiptmair (ETH Zürich, Switzerland)

Electromagnetic phenomena are at the heart of almost every modern technology. Thus, their accurate and fast numerical simulation becomes a key capability in industrial research and development, as computer aided design and testing assumes a central role in product development. The core task in electromagnetic simulation boils down to the approximate solution of boundary value problems arising from Maxwell's equations. This bland description conceals a host of really challenging problems. Important issues concern the proper discretization both in a finite element and boundary element framework, the robustness of the methods with respect to small wavelengths, the design of fast and robust iterative solvers, the incorporation of sources and lumped devices, to name only a few. Mathematics has contributed significantly to tackling these issues, and will continue to play a crucial role as rapid advances of technology and increasing computer power raise fresh challenges.

This industry day will make it possible to catch a glimpse of some current issues confronted in industrial electromagnetic simulations. For some of the problems state of the art numerical techniques will be addressed, others may still be far from being solved. Thus, practitioners will be updated on modern numerical methods and researchers can get inspiration on new and relevant topics. Thus, attending the industry day lectures will be worth while for a wide range of people.

Numerical simulation of electromechanical systems: some trends and accomplishments. **Stefan Kurz** (Universität Frankfurt, Germany) EL/TID4908/015

For the development and optimization of electromechanical systems and their components numerical modeling and simulation have become indispensable tools. Numerical methods like the Finite Element and the Boundary Element method are widely used in industry. Since the requirements regarding level of details and accuracy of the models are continuously increasing, fast methods are of particular interest. Robust matrix compression techniques, both for modeling at an appropriate accuracy level as well as construction of preconditioners have gained momentum recently. In this presentation, the theoretical foundations are briefly reviewed, including the connection to the so-called Discrete Exterior Calculus. A solenoid actuator for Diesel injection and a claw pole alternator are considered as examples, and the usefulness of symmetry exploitation and matrix compression techniques is pointed out. Finally, some trends and open issues are reported, in order to stimulate further research and industry collaborations.

Mathematical challenges for commercial high-frequency electromagnetic simulation tools. **Peter Thoma** (Computer Simulation Technology, Germany) EL/TID4909/015

The design of high speed electronic devices becomes less and less feasible without the efficient application of electromagnetic simulation techniques. Increasing packaging densities demand for robust full three dimensional solutions which require the application of general finite element, boundary element or finite difference techniques. Those methods typically lead to huge systems of equations with many millions of unknowns which need to be solved without user interaction. A close cooperation between software developers and mathematical research groups is essential in order to provide state-of-the-art solutions for these challenging problems. The talk will provide an overview of a number of industrial applications together with the currently applied corresponding solver technology. Finally a short summary of open mathematical challenges will be given which should provide some links to potential cooperation areas.

High-order scattering solvers and surface representation algorithms. **Oscar Bruno** (California Institute of Technology, USA) EL/TID4887/015

I will consider algorithms and methodologies for the numerical solution of problems of scattering by complex bodies in three-dimensional space, and I will focus on a newly developed class of high-order algorithms for these problems. These methods, which are based on integral equations, high-order integration, fast Fourier transforms and highly accurate high-frequency methods, can be used in the solution of problems of electromagnetic and acoustic scattering by surfaces and penetrable scatterers, even in cases in which the scatterers contain geometric singularities such as corners and edges. In all cases the solvers exhibit high-order convergence, they run on low memories and reduced operation counts, and they result in solutions with a high degree of accuracy. In this talk I will describe the basic methodologies inherent in these approaches. In particular, I will touch upon a new class of high-order surface representation methods introduced recently which, starting from point clouds or CAD data, can produce high-order-accurate surface parametrizations and associated surface/volume finite-element representations, suitable for high-order numerical simulations, of complex engineering surfaces in three-dimensional space.

Numerical challenges in the simulation of electrical arcs. **Henrik Nordborg** (ABB Corporate Research, Switzerland) EL/TID5017/159

The electrical arc is important in many technical applications, both for providing basic functionality (arc furnaces, plasma torches, arc welding) or as an unwanted result of electrical breakdown. The numerical simulation of arcs in real engineering application is difficult for a number of reasons. First, the three-dimensional geometries are complex enough to make a pure electromagnetic or flow simulation challenging. Secondly, the electromagnetic solver has to cope with the coupling to the gas flow, huge differences in electrical conductivity, and, in particular, continuously vanishing conductivity at the edge of the arc. Finally, the problems are always transient, requiring of the order to 10'000 time steps per simulation. The presentation will outline the main numerical challenges of this problem, with special emphasis on the electromagnetic part.

Food Processing, Talks

FP/DID3954/151: Simulating flows in food processing.

Organiser: Franz Tanner (Michigan Technological University, USA)
Co-organiser: Erich Windhab (ETH Zürich, Switzerland)
Co-organiser: Marco Dressler (ETH Zürich, Switzerland)

Deformation, orientation and breakup of droplets in flows. **Kathleen Feigl** (Michigan Technological University, USA) FP/TID4693/156

Immiscible multiphase fluid systems, such as emulsions and polymer blends, are encountered in manufacturing processes in a variety of industries. In particular, in dispersing processes, droplets of one fluid are oriented, deformed and broken up in another fluid. The properties of the final product depend, in part, on the shape, orientation and size distribution of the disperse phase droplets. In this talk, the orientation, deformation and breakup behavior of viscous droplets under various flow, fluid and interfacial conditions is discussed. The focus is on the effect of the imposed flow type or dispersing device, the viscosity ratio, the capillary number (ratio of viscous forces to interfacial tension) and, in the presence of surfactants, surface gradients in interfacial tension (e.g., Marangoni stresses). Results are presented from both numerical simulations and experiments.

Relationship between rheology and microstructure of emulsion systems in an extrusion flow. **André Braun** (ETH Zürich, Switzerland), Marco Dressler (ETH Zürich, Switzerland), Erich Windhab (ETH Zürich, Switzerland) FP/TID5046/156

Recently, a mathematical model describing polymer blends with droplet morphology was derived within the framework of non-equilibrium Thermodynamics by Dressler and Edwards[1]. The model allows to predict the difficult interplay between fluid dynamics, droplet morphology and the non-linear viscoelastic properties of the blend. The complex set of nonlinear, coupled differential equations are solved computationally for a mixed Couette/Poiseuille flow as encountered in the metering section of a single screw extruder. In our code we consider both the mixing flow perpendicular to the flights of the extruder and the conveying flow parallel to the flights. We have performed calculations for different model (e.g., blend component viscosity ratio) and flow geometry parameters (e.g., helix angle of the extruder screw). Macroscopic flow characteristics such as the volumetric throughput, the residence time distribution function, and the non-Newtonian flow stresses are discussed along with microscopic characteristics of the blend such as oblate/prolate configurations of the droplets, break-up/coalescence rates, and matrix micro-structural characteristics.

The results from this modeling / simulation approach have been applied in order to investigate correlations with partial coalescence phenomena of fat globules in ice cream extrusion processing.

General Session 1 Topic Discussion. **Marco Dressler** (ETH Zürich, Switzerland) FP/TID5048/156

FP/DID3954/151: Simulating flows in food processing. #2

Organiser: Kathleen Feigl (Michigan Technological University, USA)
Co-organiser: Erich Windhab (ETH Zürich, Switzerland)
Co-organiser: Marco Dressler (ETH Zürich, Switzerland)

(For abstract, see session #1 above.)

Design of static mixing reactors by CFD. **L Moser** (ProCeng Moser GmbH, Switzerland) FP/TID5052/156

Auslegung von Misch-Reaktoren mittels CFD

In der Kunststoffchemie werden CSE-XR Mischreaktoren der Firma Fluitec Georg AG eingesetzt. In diesen Reaktoren werden Kunststoffschmelzen innig gemischt, polymerisiert und die entstandene Wrme wird abgeführt. Die Reaktoren stehen unter einem Betriebsdruck von ber 250 bar. Die Polymerschmelzen verhalten sich strukturviskos. Messungen der abgeführten Wärme, der Verweilzeit sowie die Mischeigenschaften sind schwierig. Mittels CFD Simulationen konnten Reaktoren mit verschiedenen Grössen für unterschiedliche Polymerschmelzen untersucht und ausgelegt werden.

Eine Herausforderung stellt dabei die Beschreibung des Viskosittsverhaltens sowie die Grsse der Modelle dar. Das Produkt ändert seine Viskosität in Funktion der Scheerrate und der Temperatur.

Die Netze umfassen mehr als 22'000'000 Zellen. Das Viskositätsverhalten des Produktes wurde mittels UDF's gelöst. Die Simulationen werden auf dem Linux Cluster mit mehreren CPU's der ProcEng Moser GmbH durchgeführt.

Viscous and non-Newtonian mixing processes: what can CFD bring?. **Philippe Tanguy** (École Polytechnique de Montréal, Canada), Mourad Heniche (École Polytechnique de Montréal, Canada) FP/TID5047/156

This paper will highlight the capabilities and advantages of the virtual finite element method based on the fictitious domain method with distributed Lagrangians to tackle mixing problems involving complex kinematics, multiple impellers and non-Newtonian rheologies. Three examples will be discussed, namely two Multi-Shaft Mixer technologies, i.e. the dual shaft concentric coaxial mixer and the dual shaft eccentric mixer, and one example of a Single-shaft Multifunctional Impeller Mixer, namely the Maxblend technology from Sumitomo.

The presentation will be divided in two parts: a theoretical section dealing with an up-to-date summary of the most recent variational formulation, discretization techniques and algorithms, and an application section where the performance of the mixers will be thoroughly analyzed based on the above methods. Results will be compared with experimental data showing the usefulness of the numerical approach to handle complex mixing problems.

Modeling and simulation of sprays in food processing. **Franz Tanner** (Michigan Technological University, USA) FP/TID4716/156

Sprays are widely used in food processing, usually to produce a powdered substance with particular properties. Sprays consist of liquid and/or solid particles which move in a gaseous environment. They are modeled as dispersed multiphase flows in the turbulent flow regime, where the dispersed particles interact with each other and the environment, and undergo phase changes. This complex state of affairs is described by a set of differential equations together with appropriate state equations and initial and boundary conditions.

The gas phase is described with the three-dimensional Reynold–Favre-averaged conservation equations for species, mass, momentum and energy, in combination with a turbulence model. The liquid phase is formulated as a stochastic evolution law of the normalized particle flux which is governed by the various phenomena such as particle–particle and particle–gas interactions, as well as phase changes such as solidification and/or evaporation. In order to describe properly these processes, the change in the spray state variables, given by the particle position, velocity, temperature, size and deformation parameters, is determined by sub-models involving the aforementioned particle–particle and particle–gas interactions, subject to initial and boundary conditions for the particle states.

The coupling between the dispersed phase and the gas phase is achieved by means of appropriate source terms in the gas equations. These source terms are obtained from the spray variables by integration of the mass, momentum and energy values over all particles at a given position and time.

In this talk, an overview of today's state-of-the-art spray modeling will be presented, and various modeling aspects, including validations with experimental data, will be discussed. Further, results from spray simulations of real-world problems will be presented.

General Session 2 Topic Discussion. **Marco Dressler** (ETH Zürich, Switzerland) FP/TID5049/156

Pharmaceutics, Plenary Talk

PH/IT4994: *Does a rational way for designing a blockbuster drug exist?*
Walter Schilling (Hoffman-La Roche, Switzerland)

Current strategies and processes for designing drugs, hopefully blockbusters, are reviewed and supported by actual examples within a historical context.

Pharmaceutics, Talks

PH/DID4323/015: **Predicting the blockbuster in pharmaceutical design.**
Organiser: Gerd Folkers (Collegium Helveticum, Switzerland)

Simulation of how a drug molecule interact with its counterpart in the body, usually termed *receptor*, has been one of the major interests in pharmaceutical research over the last three decades. Meanwhile the simulation techniques have reached certain sophistication at the molecular level, due to fast computers, fast algorithms and fast high-resolution spectroscopy. Hence, useful attempts are made to investigate the drug's fate and the body's response at a very early stage of the drug development process in virtual space. The more knowledge is gained before the new chemical entity enters the clinics, the ore precise, predictive and safer the clinical studies and the lower the attrition rate will be.

The term blockbuster usually describes a drug whose global turnover exceeds one billion USD and marks the goal of development of new drugs by the large pharmaceutical companies. However, prediction tools for living systems, are necessarily reductionistic and expensive complementary sets of experiments are indispensable. Therefore, new simulation technologies to understand the phenomenon of molecular similarity in respect to biological activity, to cover specificity of drug-receptor interaction and in parallel help to understand closely-related drug toxicity are the front-line of research.

Predicting the next blockbuster: in silico *techniques for bio-activity profiling of drug candidates.* **Thierry Langer** (Inte:Ligand, Austria) PH/TID4882/159

In silico or virtual screening has gained a high impact for the efficient discovery of novel potential bio-active compounds in modern pharmaceutical research. The concept of chemical feature-based pharmacophore models has been established as state-of-the-art technique for characterizing the interaction between a macromolecule and a potential ligand. While in ligand-based drug design, feature-based pharmacophore creation from a set of bio-active molecules is a frequently chosen approach, structure-based pharmacophores are still lacking the reputation to be an alternative or at least a supplement to docking techniques. Nevertheless, 3D pharmacophore screening bears the advantage of being faster than docking and to transparently provide the user with the relevant information that is used by the screening algorithms to characterize the ligand-macromolecule interaction. As an extension of such an approach, we have successfully introduced parallel pharmacophore-based screening as an in silico method to predict the potential biological activities of compounds by screening them with a multitude of pharmacophore models. We present an overview of our technology together with the results of an application example employing a set of antiviral compounds that were submitted to in silico activity profiling using our pharmacophore building platform LigandScout. The results of the screening experiments show a clear trend towards correct prediction of activity profiles.

The challenge of predicting drug toxicity in silico. **Angelo Vedani** (Biographics Laboratory 3R, Switzerland) PH/TID4438/159

Poor pharmacokinetics, side effects and compound toxicity are frequent causes of late-stage failures in drug development. A safe in silico identification of adverse effects triggered by drugs and chemicals would be highly desirable as it not only bears economical potential but also spawns a variety of ecological benefits: sustainable resource management, reduction of animal models and possibly less risky clinical trials. In computer-aided drug discovery, both existing and hypothetical compounds may be studied; the methods are fast, reproducible, and typically based on human bioregulators, making the question of transferability obsolete. In the recent decade, our laboratory contributed towards the development of in silico concepts (automated flexible docking, multi-dimensional QSAR) and validated a series of "virtual test kits" based on the estrogen, androgen, thyroid, aryl hydrocarbon, glucocorticoid and peroxisome-proliferator activated receptor (endocrine disruption, receptor-mediated toxicity) as well as on the enzyme cytochrome P450 3A4 (metabolic transformations, drug-drug interactions). The test kits are based on the three-dimensional structure of their target protein or a surrogate thereof and were trained on a representative selection of 538 substances. The underlying 6D-QSAR technology is based on a genetic algorithm and a directional force field. Subsequent evaluation of 157 compounds different therefrom showed that binding affinities are predicted close to experimental uncertainty. These results suggest that our approach is suited for the in silico identification of adverse effects triggered by drugs and chemicals and encouraged us to compile an Internet Database for the virtual screening of drugs and chemicals for adverse effects. Details and results can be found under http://www.biograf.ch/index.php?id=projects

Computational approximations for large and complex biochemical processes. **Markus Hegland** (Australian National University), Kevin Burrage (University of Queensland, Australia) PH/TID4941/159

Computational investigations of stochastic biochemical processes require the computation of features like moments, correlations and modes. While these features can be obtained using a statistical investigation of repeated simulations they are directly obtained from the finite dimensional probability distributions which characterize the stochastic process. However, any attempt to determine these probability distributions faces the challenge posed by the extreme size of the state space of biochemical systems which is a consequence of the curse of dimensionality. We will discuss some approximations which can be applied to deal with this challenge. In particular we reduce the size of the state space by aggregating groups of states into a single state and we address the curse of dimensionality using a sparse grid approximation. Using this approach we have been able to model a simple gene regulatory cascade with 100 protein species.

The whys and hows of stochastic modelling of biochemical systems. **Kevin Burrage** (University of Queensland, Australia) PH/TID4937/159

Noise is a fundamental phenomenon in many biological systems including gene regulation. Noise can adversely affect cell function but it can also be a source of robustness, signal amplification and selection of signalling pathways. In this talk we discuss how intrinsic noise can be modelled in biochemical systems via the use of nonlinear discrete Markov processes. We will also show how delay, vital in the modelling of transciption and translation, can be put into this framework. We will illustrate these ideas through two applications: the MAPK cascade (which can be viewed as a multiscale model, linking the plasma membrane and the cytosol) and the Hes1 gene as a molecular switch (viewed as a fine scale model with delay and intrinsic noise).

Risk Management, Plenary Talks

RM/IT4861: *In full swing: optimizing portfolios of flexible gas contracts*
Oleg Zakharov (Lacima Group, UK)

After presenting a brief history of gas markets and the origin of swing contracts we discuss realistic examples of swing contracts and Stochastic Dynamic Programming approaches in optimizing a single swing contract. Further topics treated are the importance of hedging in forward markets and liquidity considerations and the value optimization conditional on limited risk.

RM/IT4857: *Generation of consistent market and credit scenarios: the calibration of a geometric model*
Simone Farinelli (UBS, Switzerland)

A scenario generator for both market and credit risk drivers is developed. On the basis of historical data, financial time series are projected into the future. The foundations were given in 1998 by Andrew Smith, who developed a coherent mathematical framework applicable to all stochastic investment models, allowing for features commonly believed to be essential and/or desirable: positive interest rates, mean reversion (where appropriate), full term structures, efficient markets, absence of arbitrage. The model consists of two parts:

- a geometrical part, where the concepts of gauge, deflator and term structure for every quantity modelled is introduced; and
- a stochastic part, where a stochastic model is applied to a minimal set of gauges (called *principal gauges*) to generate the scenario simulations.

The stochastic part is calibrated for the special choice of a VARMA model.

Risk Management, Talks

RM/DID4856/000: **Risk management in financial and energy markets.**
Organiser: Walter Farkas (ETH Zürich, Switzerland)
Co-organiser: Juri Hinz (ETH Zürich, Switzerland)

Since 1998 ETH Zurich is hosting each year a Risk Day. The aim of the 2007 Risk Day, embedded as an Industry Day within ICIAM07, is to provide a forum for the discussion of new research and technical developments in risk management in financial and energy markets. The organizers have invited outstanding experts and practitioners to present and discuss the latest advances and new thinking in the fascinating area of risk management.
More information: http://www.math.ethz.ch/finance/Risk-Day-2007.html

Tests of covariance matrices. **Jens Wiedmann** (LGT Capital Management, Switzerland) RM/TID4858/x

How can it be decided, which kind of estimator of covariance matrices is more suitable to reflect the expected portfolio risk. A kind of Maximum-Likelihood-test is introduced for solving this problem. Some concrete test results concerning different bond portfolios are shown. For these bond portfolios the simple historic covariance matrix and covariance matrices of two-factor- and three-factor-models has been tested.

Risk-based capital models in life insurance. **Hans-Juergen Wolter** (Swiss Life, Switzerland) RM/TID4859/x

A number of recent initiatives such as the preparation for Solvency II for instance have led to an increase in the extent to which insurance companies manage their risk and capital. Until now, economic capital models have been developed by the best part of the global insurance industry; it is no longer the domain of the sophisticated insurance undertakings. And yet the design of economic capital models is still under way. The aim of this talk is to discuss the characteristics of proper capital models. Often, the requirements are controversial. A model that is impeccable from a conceptual point of view might be hard to implement. We conclude with some remarks on risk measurement, motivated by the fact that some European insurance regulators have begun to demand for multi-period risk measures.

Strategic risk management: ideas and questions. **Jörg Behrens** (Ernst and Young, Switzerland) RM/TID4860/x

While risk management is highly sophisticated and forms an integral part of the financial services industry, most firms still struggle to benefit from their analytical know-how when it comes to strategic planning. We discuss problems and ideas to bridge the gap between the two worlds.

RM/DID4856/000: **Risk management in financial and energy markets.** #2
Organiser: Hans-Jakob Luethi (ETH Zürich, Switzerland)
Co-organiser: Walter Farkas (ETH Zürich, Switzerland)
Co-organiser: Juri Hinz (ETH Zürich, Switzerland)

(For abstract, see session #1 above.)

Gas portfolio and transport optimization. **Alexander Boogert** (Essent Trading BV, The Netherlands) RM/TID4862/x

The transport of natural gas has received significant attention in the last months with the large price spikes in the UK facing sudden cold weather and the flow stop from Russia to Ukraine. Transport is a necessity in a world where gas sources are far removed from the gas demand, and in which a gas portfolio easily spans several countries. Meanwhile, the range of options within a gas portfolio is growing with an increasing number of instruments and increasing international gas trading. This has led to a situation where decisions have become non-trivial. The objective of this article is to describe the construction of an integrated approach for gas portfolio and transport optimization.

Investment models in restructured electricity markets subject to risk. **Yves Smeers** (Université Catholique de Louvain, Belgium) RM/TID4863/x

Capacity expansion optimization models dominated the area of investment in generation during the former days of the regulated electricity sector These models have lost some of their appeal today and other tools , some inspired by the theory of real options, have replaced them. We reconsider the old capacity expansion model that we expand into equilibrium models in a risky environment. For the sake of tractability and robustness we assume no market power. We first model risk by assuming firms with different cost of capital; this equilibrium model deviates minimally from the usual capacity expansion model (which assumes a single cost of capital). Alternatively we also consider that the risk attitude of firms is represented through risk functions; this forces one to consider a stochastic equilibrium model. We compare the approach to equilibrium (not optimization) models of the real option type.

Telecommunications, Plenary Talk

TC/IT4921: *Future challenges in mobile telecommunication industry*
Hartmut Kremling (Vodafone D2 GmbH, Germany)

Since the mobile telecommunication industry is suffering from saturated markets, customer's demands are rising. Market shares are allocated based on tariffs, network quality and the variety and quality of offered services. Therefore changes and innovations are omnipresent. Mobile operators are facing a variety of challenges in operating their existing networks and deploying future network technologies. On one hand convergent services, increasing bandwidth demand and significantly evolving traffic patterns due to new multimedia services require additional network resources and more complex network topologies. On the other hand, increasing cost pressure forces operators to streamline their network in order to allow for a more efficient design and operation. Thus optimisation methods become increasingly important to design, build and operate cost efficient networks and to cope with the expected customer demands for the future. Based on novel network standards and all IP, novel broadband services need to be invented in order to generate customer demands and service usage. Services like VoIP, IPTV, location-based and personalised services and advertising are the future. Increasing media consumption and mobile-internet convergence will be achieved by user-friendly communication portals and convergent multimedia services. Network and service innovations will only be successful, if increasing complexity and dimensionality are reduced by powerful algorithms for compression and customer profiling.

Telecommunications, Talks

TC/DID4906/015: **Optimization of telecommunication infrastructure.**
Organiser: Martin Grötschel (Zuse-Institut Berlin, Germany)

Optimization/equilibrium problems coming from regulation process in the mobile telecommunication industry. **Alejandro Jofré** (Universidad de Chile) TC/TID4917/015

Computing access charges in economic regulation process for a mobile telecommunication industry requires in many countries the optimal design of an efficient representative mobile telecommunication company providing communication services to satisfy the demand. For these companies the access charges usually represent an important percentage of their incomes. In this talk we show how the computation of the access charges requires optimization/equilibrium models connecting the demand, the optimal design of networks (antennas, switches) and financial computation aspects. We show then how the level of access charges affect the demand producing an iterative equilibrium process whose solution have an interesting economic meaning. This Optimization/equilibrium procedure is being currently used for a couple of regulators and it is particularly important for countries where the demand for mobile telecommunication services is strongly increasing.

Joint design and pricing on a network. **Martine Labbé** (Université Libre de Bruxelles, Belgium) TC/TID4918/015

In order to optimize revenue, service firms must integrate within their pricing policies the rational reaction of customers to their price schedules. In the telecommunication industry, this process is all the more complex due to interactions resulting from the structure of the supply network. In this paper, we consider a streamlined version of this situation where a firm's decision variables involve both prices and investments. We model this situation as a joint design and pricing problem which we formulate as a mixed-integer bilevel program, and whose properties are investigated. In particular, we take advantage of a feature of the model that allows the development of an algorithmic framework based on Lagrangean relaxation. This approach is entirely novel, and numerical results show that it is capable of solving problems of significant sizes.This is joint work with Luce Brotcorne, Patrice Marcotte, and Gilles Savard.

Network design with multi-period pricing: modelling and solution techniques with computations for the case of optical backbone networks. **Iraj Saniee** (Alcatel–Lucent Bell Laboratories, USA) TC/TID4919/015

We describe telecommunication network design models in which demand is an endogenous variable and affects and is affected by equilibrium prices of service and bandwidth. We assume that the network operator must make investment decisions over a multiperiod planning horizon while facing possible changes in technology, typically involving a steadily decreasing per-unit cost of capacity. In these talk we deviate from the traditional monopolistic models in which demand is given as an exogenous input parameter, and the objective is to minimize capacity deployment costs. Instead, we assume that the carrier sets end-to-end prices of service and bandwidth at each period of the planning horizon, which determine the demands that are to be met, using a plausible and explicit price-demand relationship. The resulting demands must then be routed, requiring an investment in capacity. The objective of the optimization is now to simultaneously select end-to-end prices of service and bandwidth and network installed capacities at each period of the planning horizon, so as to maximize the overall net present value of expanding and operating the network. The resulting optimization problems pose significant challenges to standard optimization techniques. The complexity of the model, its nonlinear nature, and the large size of realistic problem instances motivate the development of efficient and scalable solution techniques. We illustrate the modeling and solution techniques and approximations that we have used for the case of large-scale optical networks with protection requirements and compare and contrast with solutions derived from some existing non-linear optimization packages.Parts of this presentation are based on joint work with Daniel Bienstock, Olga Raskina and Qiong Wang.

Planning of optical core networks. **Joerg Eberspaecher** (TU München, Germany) TC/TID4920/015

Wavelength-division multiplexing (Wdm) technology in optical core networks enables very high bitrates and increased flexibility. To be prepared for new multimedia services and the increasing cost pressure network providers are forced to plan their networks carefully, not only before deployment, but also during the operation (online-planning). Network planning is a complex process that involves a number of subtasks which are typically strongly dependent on each other. The topological planning determines the location of switching nodes and where fiber links have to be provided. Based on this physical infrastructure and a given traffic matrix it is possible to perform the routing of demands. In order to be able to compensate for

network failures, it is essential to allow for alternative paths between the nodes. Hence, the physical network structure must be sufficiently meshed to allow for route diversity. Another routing aspect is the signal quality along the transmission path to guarantee a certain quality-of-service. The advent of transparent end-to-end transmission by optical signal switching at nodes poses additional requirements for transmission engineering since we have to take into account signal attenuation, dispersion, and nonlinear fiber effects.This talk gives an overview of optical core network planning. It presents typical modeling tasks of the design process and sketches the main methods currently applied in network planning. The typical design goal is to minimize total network costs in terms of investment costs (capital expenditures CAPEX) and also operational expenditures (OPEX). In order to provide optimal network configurations, mathematical programming is a well suited technique that is often applied to planning tasks. Depending on the network modeling, linear, integer linear as well as nonlinear programs can be used.However, the computational complexity and time critical issues such as online network configuration often require solutions based on fast heuristics. Generally, it is crucial to decompose the complex planning process into adequate subproblems that can be solved independently of each other. In the talk we present typical design problems, show solution examples and list a number of open issues which can best be tackled by joint efforts of network designers, system engineers, and scientists from mathematics.

TC/DID4906/015: Optimization of telecommunication infrastructure. #2

Organiser: Martin Grötschel (Zuse-Institut Berlin, Germany)

(For abstract, see session #1 above.)

Optimization of 2G/3G radio networks. **Andreas Eisenblätter** (Atesio GmbH, Germany) TC/TID4907/015

The development of wireless mobile communications over the past decade is breathtaking. So are the multi-billion Euro investments of radio network operators for establishing and maintaining high quality network infrastructure. Mathematical optimization has proven to be a very powerful instrument for designing cost efficient networks and for tuning network quality (prior to roll-out as well as during operations). This talk highlights impressing examples from projects with GSM and UMTS network operators. These success stories build on the ability to identify appropriate system models and on the availability of powerful mathematical optimization tools. They also illustrate the importance of close collaboration among radio engineering experts and mathematicians.

Efficient multi-carrier transmission: reflexive subspace of L_1 and Szemerédi's theorem on arithmetic progression. **Holger Boche** (Fraunhofer HHI Berlin, Germany) TC/TID4923/015

Multicarrier transmission is a very prominent transmission technique for wireless communication systems. The basic idea is to use the orthogonal Fourier system for the information transmission. One important problem in application of multicarrier transmission is to control the peak-to-power ratio; i.e., the L_1-norm of the transmission signal. One approach to solve the peak to average power reduction problem is to select a certain subset of the Fourier system for the information transmission and to use the complementary subset of the Fourier system for the peak to average power reduction. This is closely connected with the problem of characterizing the reflexive subspace of L_1. Szemerédi's theorem on arithmetic progression is used to analyse the properties of the chosen subset of the Fourier system for the information transmission.

Geometric routing in mobile ad hoc *networks.* **Francois Baccelli Baccelli** (École Normale Supérieure de Lyon, France) TC/TID4924/015

Geometric/geographic informations can be used to design new distributed multi-hop routing algorithms for mobile ad hoc wireless networks.In a first typical example, when a given packet is located at some tagged node, the next hop on the packet's route is chosen as the nearest among the nodes which are closer from the packet's destination than the tagged node. In a second typical example, one selects as next hop the node being the closest to the destination among the set of nodes which receive this packet successfully when broadcasted by the tagged node. Such algorithms can be used both in the point to point case and in the multicast case.The aim of this talk is to review a few analytical results which were recently obtained on such routing algorithms using stochastic geometry. Within this framework, random routes are built on realizations of homogeneous Poisson point processes of the Euclidean plane. The geometry of these routes can be analyzed thanks to the locality of next hop definition and the mean performance of the algorithms can then be characterized via averages computed over all Poisson configurations.

Optimization models and methods for designing wireless local-area networks. **Edoardo Amaldi** (Politecnico di Milano, Italy) TC/TID4922/015

Wireless Local Area Networks (WLANS) are becoming pervasive in working environments as well as public areas. Their rapid spread and increase in size call for quantitative methods to support decisions in designing high-performance WLANS. Considering as efficiency measure the sum over all users of the fraction of time they can access the network, the problem of deciding access points location and channels assignment so as to maximize network efficiency gives rise to challenging nonlinear variants of the set covering problem. We discuss mathematical programming models and methods to tackle versions of the problem, which capture important features of these networks, and we report some computational results.

Different parts of this presentation are joint work with S. Bosio, A. Capone, M. Cesana, F. Malucelli and D. Yuan.

Transport Systems, Talks

TR/DID1099/015: **Modelling and simulation of transport systems.**

Organiser: Michel Bierlaire (École Polytechnique Fédérale de Lausanne, Switzerland)

The complexity of transportation systems requires advanced mathematical models and algorithms to assist in their design, implementation and operations, as well as efficient and user-friendly pieces of software.

Although conceived and developed mainly in the academic community, advanced techniques have made their way to the industry, and are now distributed by various companies. These companies not only have contributed to the transfer of knowledge and technology to practionners, but are also active in research and developement.

The objective of this industry day is to present some of these companies, discuss the challenges associated with the use of advanced mathematical models in practice, and identify how industries and researchers from academia can better collaborate in the future.

Online microscopic traffic simulation to support real-time traffic management strategies. **Jaime Barcelo** (Universitat Politècnica de Catalunya, Spain) TR/TID4119/159

A timely response to incidents or other type of conflicting situations, recurrent or not, is a key requirement of any real time traffic management system, namely in large complex networks, but for a proper and improved performance of such system addtional functions are necessary: a decision making process assisting the trafic operator in identifying which could be the more appropriate management strategy to solse the identified problem; the capability of testing before implementation whether the selected strategy will have the expected impact or not and an anticipatory capability to forecast the short term evolution of traffic conditions to prevent the undesired effects of congestion. This paper presents the design and implementation of a system with these characteristics based on AIMSUN microscopic simulator and its application to some real life projects.

Optimisation algorithms for airline management . **Alberto De Min** (APM Technologies SA, Switzerland) TR/TID4573/159

APM Technologies SA is based in Geneva, Switzerland, and produces modular management software for airlines. APM products provide informed, intelligent solutions to problems related to aircraft scheduling, aircraft operations, aircraft maintenance, crew pairing, crew roster, disruption recovery and financial profitability. This talk reviews the mathematical approach followed by APM and describes the minimization algorithms implemented in its products.

A hybrid traffic-simulation model. **Andres Rabinowicz** (Caliper Corporation, USA) TR/TID4690/159

This paper describes a traffic model designed to simulate vehicles at varying levels of fidelity in an integrated hybrid modeling framework. Each of three model fidelities, including microscopic, mesoscopic, and macroscopic, is assigned to any chosen set of roadway segments, contiguous or dispersed, in a single network model and is used to simulate the movement of traffic through those segments. The microscopic model simulates individual vehicles based on a combination of sub models including car-following and lane changing. The mesoscopic model simulates vehicles as members of traffic cells and streams, their movements regulated by the density of the cell or stream of which they are a part based on speed-density relationships. Lastly, the macroscopic model uses volume-density relationships to estimate travel times, on which vehicle movements are based. The framework presented in this enables the simulation of very large networks in a way that makes the best use of available data and computing resources without having to partition the network or rely on disjoint models.

GAMM, Plenary Lectures

GA/IT5030: Richard von Mises Prize Lecture II: *Explicit high-order one-step finite-volume and discontinuous Galerkin schemes on unstructured triangular and tetrahedral meshes for hyperbolic balance laws*
Michael Dumbser (Universität Stuttgart, Germany)

In this talk we present several building blocks for the construction of arbitrary high order accurate explicit one-step schemes in time for the solution of linear and nonlinear hyperbolic balance laws with stiff and non-stiff source terms on unstructured triangular and tetrahedral meshes in two and three space dimensions. The spatial discretization operator on unstructured meshes is either based on high order accurate WENO finite volume (FV) schemes or on a high order accurate discontinuous Galerkin (DG) approach.

The main feature of the proposed schemes is the particular time-discretization, which leads to explicit one-step methods in time that automatically match temporal accuracy with spatial accuracy. The explicit one-step nature of the schemes does not only allow for an efficient MPI parallelization on modern supercomputers, but also allows the easy implementation of time-accurate local time stepping for time-dependent problems, at least when using DG space operators. For hyperbolic systems with non-stiff source terms the element-local solution is expanded within one time step in a temporal Taylor series where then the classical Cauchy–Kovalewski procedure is used to replace time-derivatives with space derivatives using repeated differentiation of the original governing PDE. Unfortunately, in the case of stiff source terms, a temporal Taylor series expansion is no longer appropriate. Thus, a new element-local space-time DG method is used for time-discretization in order to predict the time-evolution within each element locally within the current time step. This new approach allows the construction of asymptotically consistent schemes for hyperbolic PDE with stiff source terms with any desired accuracy in space and time.

Using the WENO FV space discretization operators, we show numerical convergence results up to sixth order of accuracy in space and time for the compressible Euler equations of gas dynamics on triangular and tetrahedral meshes in two and three space dimensions. Furthermore, various unsteady two- and three-dimensional flow problems with smooth and discontinuous solutions are computed to validate the accuracy of the approach and to underline the non-oscillatory shock-capturing properties of the method. As an outlook to future applications, first results for the compressible unsteady Navier–Stokes equations on unstructured triangular meshes are shown. For hyperbolic systems with stiff source terms, convergence results and several test cases underlining the asymptotically consistent behaviour of the method are also presented.

Using the DG space operators, we show numerical convergence results and applications in three space dimensions using the proposed one-step time discretizations together with the new time-accurate local time stepping approach. Applications are shown for the linearized Euler equations commonly used in computational aeroacoustics (CAA), for the Maxwell equations and for the equations of linear elasticity in heterogeneous anelastic and anisotropic media as well as for linear elasticity in porous media, where the source terms in the governing PDE may become stiff in the low-frequency range.

GA/IT5031: Richard von Mises Prize Lecture I: *Model reduction of differential-algebraic equations*
Tatjana Stykel (TU Berlin, Germany)

Model order reduction play a significant role in simulation, control and optimization of large-scale differential–algebraic equations (DAEs) that arise in computational fluid dynamics, circuit simulation and multibody dynamics. The aim of model reduction is to approximate a large-scale dynamical system by a reduced-order model that captures the main features of the original system and has a small approximation error. In this talk we give an overview on model order reduction techniques for linear DAE systems and demonstrate their performance on practical problems.

GA/IT4717: *Quasi-continuum orbital-free density functional theory: a route to multi-million-atom electronic structure calculations*
Kaushik Bhattacharya (California Institute of Technology, USA)

This talk will describe a method for doing electronic structure calculations at macroscopic scales. Density functional theory, a formulation of quantum mechanics, has provided insights into various materials properties in the recent decade. However, the computational complexity of this approach has made other aspect, especially those involving defects, beyond reach. We describe a method that enables the study of a multi-million atom cluster using orbital free density functional theory with no spurious physics or restrictions on geometry. The key idea is a systematic means of adaptive coarse-graining retaining full resolution where it is necessary and coarsening where it is not with no patches, assumptions or structure. We demonstrate the method, its accuracy under modest computational cost and the physical insights it offers using various examples. Our calculations reveal that multi-million atom computational samples are inevitably required for predicting bulk properties of materials from orbital-free density-functional theory.

This talk is based on joint work with Vikram Gavini and Michael Ortiz.

GA/IT4571: *Tracking control of distributed-parameter systems: from theory to applications*
Andreas Kugi (TU Wien, Austria)

In this talk some recent results on the tracking control of distributed-parameter systems (DPS) are discussed and demonstrated by means of several application examples. Thereby, we utilize the so-called two-degrees-of-freedom control structure comprising a feedforward part for reference tracking and a feedback part for stabilizing the tracking error dynamics. Basically, there exist two approaches when dealing with the controller design for DPSs. First, in the so-called early lumping approach, the DPS is discretized w.r.t. the spatial coordinates and the controller design is based on the resulting system of

(nonlinear) ordinary differential equations. This often brings along rather complex control laws and does not take into account the distributed-parameter nature in a systematic way. In contrast to this, we focus on the so-called late lumping approach where the controller design relies on the DPS and the control law is then approximated for the purpose of real-time implementation.

In recent years there have been significant advances in extending the concepts of differential flatness and passivity-based as well as backstepping control, well established for (nonlinear) finite-dimensional systems, to the infinite-dimensional case. Clearly, in contrast to finite-dimensional systems there is no general approach which applies to the whole class of DPSs. Therefore, we focus on special examples each representing a certain class of DPSs. Among these examples we present the high-dynamic motion control of a piezoelectric cantilever, the control of a trolley carrying a heavy chain, the trajectory tracking of an (unstable) diffusion–convection–reaction system with nonlinear reaction rate and the temperature control in a steel-slab.

GA/IT4791: *On unsteady boundary-layer separation*
Anatoly Ruban (University of Manchester, UK)

The boundary-layer separation problem has been a focus of attention in fluid dynamics since 1904, when Prandtl introduced the notion of the boundary layer in high Reynolds number flows. In his seminal paper, Prandtl not only formulated the boundary-layer equations, but also gave physical explanation of the flow separation as being associated with the formation of flow reversal region inside the boundary layer. This concept lies in the foundation of all subsequent studies of the boundary-layer separation, including the theory of viscous–inviscid interaction. Also known as the triple-deck theory, it was formulated simultaneously by Neiland (1969) and Stewartson & Williams (1969) in application to self-induced separation in supersonic flows.

Later many researchers were involved in the development of the theory, and it became clear that the viscous–inviscid interaction governs the flow separation in wide variety of physical situations. However, summarising the results of a century long effort in this field, one has to admit that despite the significance of the progress made, many aspects of the theory of separated flows remain unresolved. Most notably, the theory remains predominantly restricted to two-dimensional, steady flows.

In this talk we shall discuss the separation of unsteady boundary layers, when alternative forms of separation become possible; these might not even involve the flow reversal. In the first part of the talk, the so called *collisional separation* will be considered. Theoretically it may be investigated based on discontinuous solutions of the boundary-layer equations. Such solution are encountered in various physical situations. We shall show that the discontinuities (by analogy with gas dynamics, we call them *pseudo-shocks*) are the centres of the fluid eruption from boundary layers.

In the second part of the talk, we shall discuss unsteady boundary-layer separation under the conditions when it may be treated (if considered in the coordinate frame moving with the separation point) as steady separation on a moving wall. Both cases of upstream and downstream moving wall will be studied. Interestingly enough, in the former case the flow separation requires a *favourable* pressure gradient to be imposed upon the boundary layer.

GA/IT4838: *Ferrofluids: magnetically controllable liquids*
Stefan Odenbach (TU Dresden, Germany)

Complex fluids with a flow behaviour differing significantly from the behaviour of normal liquids like water or oil exhibit numerous fascinating flow effects. This becomes especially interesting if the fluids properties and flows can be controlled by external forces.

Prominent examples for fluids allowing such an external control are suspensions of magnetic nanoparticles commonly known as ferrofluids. They exhibit normal liquid behaviour coupled with superparamagnetic properties leading to the possibility to control their flow and change their properties by means of moderate magnetic fields in the order of $10\,\mathrm{mT}$. With such fields, which can be produced easily with small electromagnets or by means of commercial permanent magnets, forces comparable to, for example the gravitational force, can be exhibited to ferrofluids. The comparably easy magnetic control gave rise to the development of numerous applications of ferrofluids in various technical and medical areas which partly gained importance in everyday life.

Within the talk the origin of the magnetic influence, its fluid mechanical consequences as well as the application possibilities in mechanics, medicine and other fields will be outlined and illustrated with a couple of experiments.

GA/IT4721: *Secret and joy of configurational mechanics: from foundations in continuum mechanics to applications in computational mechanics*
Paul Steinmann (TU Kaiserslautern, Germany)

Configurational mechanics has developed into a very active and successful topic both in continuum mechanics as well as in computational mechanics over the recent years. On the continuum mechanics side the basic idea is to consider energy variations that go along with changes of the material configuration. Configurational forces are then energetically dual to these configurational changes. Configurational forces take the interpretation as being the driving forces in the kinetics of defects; like e.g., cracks, inclusions, phase boundaries, dislocations and the like. On the computational side it turns out that a discretisation scheme brings in arteficial, discrete configurational forces that indicate in a certain sense the quality; e.g., of a finite-element mesh. This information can then be used in order to optimize the nodal material positions. Surprisingly, even driven by energetical arguments, it turns out that a finite element mesh optimized with respect to discrete configurational forces also renders superiour results in terms of classical error measures. The talk will span the field from the underlying theoretical foundations over the algorithmic challenges to various computational applications.

GA/CTS4896/01: **Materials, motion and stability.**

Organiser: Martin Arnold (Universität Halle–Wittenberg, Germany)
Co-organiser: Hartmut Bremer (Universität Linz, Austria)

Die Discrete Element Method (DEM) in der Geotechnik. **Eva Heesen** (TU Hamburg–Harburg, Germany), Edwin Kreuzer (TU Hamburg–Harburg, Germany) GA/CT2121/001

Hafenanlagen werden häufig auf schlechtem Baugrund gebaut und müssen daher auf Tausenden von großen Pfählen gegründet werden. Für die Planung von Hafenanlagen ist die Tragfähigkeit der Pfähle also von entscheidender Bedeutung. Derzeit können Pfahltragfähigkeiten aber nur im Nachhinein bestimmt werden. Die Schwierigkeiten in der Vorhersage entstehen durch die starken Veränderungen der Bodeneigenschaften während der Pfahlinstallation. Ergebnisse aus bodenmechanischen Voruntersuchungen haben nur noch wenig Aussagekraft. Bis heute ist ungeklärt, welche Bruch- und Verdrängungsmechanismen bei der Pfahlherstellung das Bodenverhalten bestimmen. Klassische bodenmechanische Ansätze versagen meist komplett. Die Modellierung des Pfahlrammens mit der Finiten Elemente Methode (FEM) wiederum ist problematisch, weil derzeitige Materialmodelle die Scherfugenbildung im Boden nur unzureichend abbilden können, Scherfugen aber eine entscheidende Rolle bei der Modellierung des Nahfeldes des Pfahls spielen. Daher wird gezeigt, wie die maßgeblichen Mechanismen bei der Pfahlinstallation sowie deren Einfluss auf das Tragverhalten des Pfahls mit Hilfe der Discrete Element Method (DEM) untersucht werden können. In der DEM wird der Boden als Granulat betrachtet, das aus einzelnen Partikeln besteht, die miteinander in Wechselwirkung stehen und sich gegeneinander verschieben können. Auf diese Weise können große Verschiebungen sowie Kornrotationen problemlos modelliert und somit kann auch das Nahfeld des Pfahls adäquat abgebildet werden. In dem hier verwendeten zweidimensionalen Modell werden die Partikel als konvexe unregelmäßige Polygone modelliert. Erste Ergebnisse der Pfahlmodellierung wie z.B. Verschiebungsfelder, Kornrotationen und Veränderungen der Lagerungsdichte werden in Abhängigkeit von Pfahlrauhigkeit und Eindringgeschwindigkeit vorgestellt.

Application of the discrete-element method to model cohesive materials. **Timo Gaugele** (Universität Stuttgart, Germany), Peter Eberhard (Universität Stuttgart, Germany) GA/CT2729/001

The discrete element method (DEM) has been widely used in the past to model granular materials like powder and sand. In recent years this approach was adopted by engineers in geomechanics and civil engineering to model geomaterials like concrete or marl. However, most modeled geomaterials exhibit very brittle behavior when loaded. Here, it is investigated if the so far used approach can be advanced to model materials that exhibit ductile behavior to some extent as well. Different models based on the DEM for the simulation of cohesive materials are presented. Starting from a basic two-dimensional non-cohesive model with circular particles the model is enhanced by including massless beam elements which represent particle bonds to introduce cohesive forces between adjacent particles. The particle bonds are represented by force laws and can sustain only a specified stress until failure. By implementing different force laws it is investigated if the composite made up of bonded discrete elements displays realistic elastic properties. As the bonds can only be loaded to a certain limit a failure criterion is used to detach and remove bonds. Once a bond is detached it can never be restored. By using different failure criteria it is to be investigated if the composite exhibits qualitatively correct failure modes.

Real-time simulation of quasi-static rod deformations. **Joachim Linn** (Fraunhofer ITWM, Kaiserslautern, Germany), Thomas Stephan (Fraunhofer ITWM, Kaiserslautern, Germany) GA/CT4063/001

We present a model of flexible rods, based on Kirchhoff's geometrically exact theory, which is suitable for the fast simulation of quasi-static deformations within VR (vitual reality) or FDMU (functional digital mock up) applications. Unlike simple models of *mass & spring*-type typically used in these application areas, our model provides a proper coupling of bending and torsion. The computational approach comprises a variational formulation combined with a finite-difference discretization of the continuum model. Approximate solutions of the equilibrium equations for sequentially-varying boundary conditions are obtained by means of *energy minimization* using a nonlinear CG method. The computational performance of our model proves to be sufficient for the interactive manipulation of flexible cables in assembly simulation. A *dynamical* version of our model, which accounts for inertial effects, can also be integrated into MBS environments to provide a fast simulation of flexible rod-like structures.

On stability problems of the space elevator. **Michael Schwarzbart** (TU Wien, Austria) GA/CT2366/001

We investigate the stabilty of steady-state motions of an extremely long cable in circular orbit around the Earth. Possible applications of such a cable are to use it as track of an Earth to space elevator or to lift payloads with the cable rotating in its orbital plane. These are also two typical examples for a classification of synchronous and non-synchronous ([1]) motions of the cable. We consider both cases and formulate, first, the stability problem of the motion of an anchored synchronous cable for small motions of the pivot point, which might be necessary to avoid a collision with a low orbit spacecraft. Secondly, we study also the stability of the motion of a nonsynchronous rotating cable ([1]) with a length of the order of 1/3 of the diameter of the Earth. The realisation of these elevator concepts became feasible technologically at about 1990 when a new high strength and low weight material, called carbon nanotubes, was discovered. For our numerical calculations we assume defective carbon nanotubes with more realistic technical material properties ([2]).

A holistic finite-element and multi-body-systems approach for the virtual product development. **Corinna Barthel** (Universität Magdeburg, Germany) GA/CT4078/001

The enhancement and application of a holistic virtual product development process is one of today's main research and development activities in engineering due to the expected reduction of time and costs and the improvement of the product quality.

The paper first presents the results of an automated generation of adaptive mechanical models, including the derivation of qualified submodels and their integration into a holistic model. The focus is on the application of a multi-body systems (MBS) approach in connection with finite element analysis (FEA) and control.

In general the modelling starts with CAD-based geometry data which have to be extended by parameters determining the physical and functional behaviour of a system. In dependence of the specific tasks to be solved, different types of models can be derived, such as a precise local model, if the local stresses distribution is required or a rough overall model, if the trajectory of the motion of a mechanical system is in the focus of the investigation. The type of model, which is created by the engineer, significantly affects the quality of the results. Consequently, this process should be automated to a possible extent and controlled by error estimates.

In the paper it is shown, that a combination of a multi-body systems approach including different elastic finite element models as well as multi-field sub-models and also control results in a sufficiently accurate model designed for solving a large variety of engineering problems. The presentation and verification of the results in a virtual reality environment show the advantages of such approach for an effective product development process.

The numerical analysis of the trapezoidal thread rolling process . **Maciej Kukielka** (Koszalin University of Technology, Poland), Leon Kukielka (Koszalin University of Technology, Poland) GA/CT2727/001

The thread rolling is difficult technological process. Improve quality and contemporary reduce manufacture cost of the trapezoidal thread expect knew of physical phenomena observed in the contact zone between rolls and deform workpieces. Therefore, this paper presents the physical and mathematical models of deformations (displacements and strains) and stress in the cold process of trapezoidal thread rolling. The process is considered as a geometrical and physical nonlinear, initial as well as boundary value problem. The phenomena on a typical incremental step were described using a step-by-step incremental procedure, with an updated Lagrangian formulation. The state of strains was described by Green-LagrangeŠs tensor, while the state of stress by the second symmetrical Pioli-KirchhoffŠs tensor. The object was treated as an elastic (in the reversible zone) and visco-plastic body (in non-reversible zone) with mixed hardening. The variational equation of motion in three dimensions for this case was proposed. Then, the finite elements methods (FEM) and dynamic explicit method (DEM) were used to obtain the solution. The application developed for the method of finite elements ANSYS, which provides a complex time analysis for displacement, strains and stresses occurring in the object. The recommendations concern modeling the trapezoidal thread rolling process, where reduce degrees of freedom in numerical model is very important and provide convergence calculated results for maximum stress and strain values in the thread surface layer, were elaborate. The influence a various process conditions on the states deformation and stress for examples calculations, were presented.

GA/CTS4893/01: Vehicle dynamics.

Organiser: Peter Eberhard (Universität Stuttgart, Germany)

Co-organiser: Hartmut Bremer (Universität Linz, Austria)

Recent developments in flexible multibody dynamics. **Andreas Heckmann** (DLR Aerospace, Germany), Ingo Kaiser (DLR Aerospace, Germany), Matthias Reiner (DLR Aerospace, Germany) GA/CT1704/001

In present days new technologies emerge and the demands on technical systems increase. Environmental issues such as noise gain more and more importance and the complexity of products is perpetually enlarged so that more technical domains are involved in the design process. These facts give reason to extend the modelling capabilities in flexible multibody dynamics concerning three different issues, namely (i) the consideration of thermoelastic behaviour, (ii) the dynamic rotor analysis for vibroacoustic post-processing and (iii) the acasual, symbolic modelling of flexible bodies for heterogeneous technical systems. All these extensions are aligned with the goal to incorporate the analysis of flexible bodies in a design process with many different demands and needs.

(i) Mechanical processes are often associated with heat generation due to friction or energy transformation. E.g. in friction brakes the heat generation is even at the core of the process and may feed back on the mechanical behaviour. With this background, the proposed modal multifield approach provides an efficient way to consider the thermoelastic properties of flexible bodies.

(ii) According to the so-called arbitrary Lagrangian-Eulerian (ALE) representation of flexible bodies, the motion of an elastic rotor may be decomposed in a specific way, so the reference frame is neither fixed in space nor connected with material particles. This approach has been found to be adequate for rolling contact problems such as a railway wheelset on rails and enables the straight-forward consideration of the gross angular motion of a wheelset for the numerical evaluation of its sound radiation.

(iii) The object-oriented, high-level modelling language Modelica, developed by the non-profit Modelica Association provides a platform to incorporate multiple modelling domains such as hydraulics, pneumatics, mechanics, electric systems etc. in one common simulation environment. In the meantime this concept is additionally substantiated by a large set of ready-to-use component libraries including the new Modelica flexible bodies library. In the course of the talk the advantages of the symbolic, acasual modelling approach of Modelica for the design of technical systems with elastic bodies will be discussed.

Modellbasierte Optimierung aktiver Radaufhängungen. **Werner Schiehlen** (Universität Stuttgart, Germany) GA/CT1368/001

Beim Entwurf von Radaufhaengungen fuer Kraftfahrzeuge haben sich Mehrkoerpermodelle, welche durch die zufaelligen Strassenunbenheiten stochastisch erregt werden, bewaehrt. Zur Berechnung der Schwingungsantwort des Fahrzeugs stehen die numerische Simulation, die Spektraldichteanalyse und die Kovarianzanaylse zur Verfuegung. Zur Beurteilung von Aufhaengungssystemen werden die Varianzen der Aufbaubeschleunigung, der dynamischen Radlasten und des Arbeitsraumes der Radbewegung benoetigt, um Fahrkomfort und Fahrsicherheit zu bewerten.

Die Kovarianzmethode wurde fuer passive Radaufhängungen erfolgreich angewandt. Heute stehen jedoch die aktiv geregelten Radaufhaengungen im Mittelpunkt des Interesses, wobei die regelungstechnischen Methoden des Zustandsraums und des Frequenzgangs eingesetzt werden ohne die Varianzen zu beruecksichtigen.

In diesem Beitrag wird die Kovarianzanalyse auf aktive Radaufaengungen erweitert mit "Skyhook" Daempfern und aktiven Federn. Das Ergebnis zeigt den Einfluss der mechanischen Einwurfsvariablen Masse, Steifigkeit und Daempfung sowie der Reglerverstaerkungen auf. Damit laesst sich die Parameterempfindlichkeit der Entwurfsvariablen betimmen.

An optimal control algorithm for an autonomously driving car. **Matthias Gerdts** (University of Birmingham, UK) GA/CT2706/001

The driver of an automobile can be modeled by formulating a suitable optimal control problem. However, if the length of the drive is very long or if the course has a very complicated structure, the numerical solution of the optimal control problem becomes very difficult. Therefore a moving horizon technique is employed, where the global optimal control problem is splitted into a sequence of local optimal control problems which are combined by suitable continuity conditions.

We will report our experiences with this algorithm as it has been integrated in an existing car and allows to compute time optimal solutions for various handling courses in a robust way. The algorithm can be used for testing different setups of cars under the same conditions as the influence of a real driver is excluded.

Work-space analysis and maximal-force calculation of a face-shovel excavator using kinematical transformers. **Francisco Geu Flores** (Universität Duisburg–Essen, Germany), Andres Kecskemethy (Universität Duisburg–Essen, Germany), Alois Pöttker (Terex GmbH, Germany) GA/CT2374/001

This paper describes a method for the efficient determination of maximally allowed shovel forces for a heavy-load face-shovel excavator through its workspace. The method is based on the concept of “kinematical transformers”. In this concept, each multibody loop is regarded as a transmission element coupled by linear equations with the other multibody loops, allowing an efficient detection of closed-form kinematical solutions. Additionally, the method uses a graphical optimization approach to find the maximal digging forces for given positions of the shovel. An application-specific code has been realized using a combination of the object-oriented multibody library Mobile and symbolical equations. The method is applied to existing heavy-load excavators, showing that the computational effort can be reduced by a factor of more than 200 as compared to general purpose numerical codes.

Hybrid neural-network shock-absorber model. **Vladislav Pracný** (Universität der Bundeswehr Hamburg, Germany) GA/CT1088/001

Shock absorber is one of the main components of car’s suspension and its function is to control chassis movement. By turning the mechanical energy into heat unwanted vibrations are eliminated. As we know, the inner design of shock absorber is relativ complex, whereby the damping force is specified by the flow of damping oil through various valve assemblies. Further the temperature dependent viscos properties of damping oil, friction effects and the gas charge are effecting the damping force. The spline approach is not suitable, if all this phenomena have to be considered. Even though the spline function is widely applied in the full vehicle simulation. The principle advantages are its simplicity and optional changes of the characteristics, if e.g. influence of the shock absorber to the behaviour of the vehicle is investigated. A fairly modern approach is the neural network modelling based on the mathematical approximation of measured data. In this case, the components behaviour is described by an algebraic equation, where the information about the system is carried by a set of parameters, in general, with no physical meaning. If the parameters of the neural network are set properly, the approximation accuracy is very high. The main drawback of is the missing interpretability. To obtain accurate force prediction together with a system variability, spline and neural network approach are combined. Two forces in parallel $F_d = F_{spl} + F_{nn}$ are representing the damping force. The main velocity dependent shock absorber characteristics F_{spl} is determined by a spline function. By the neural network only the remainder force F_{nn} between measurement and spline approximation is represented. The neural network is defined as a function of immediate time history of velocity, actual displacement and actual temperature. Additionally to the force components a differential equation for the temperature evolution is defined. The hybrid shock absorber is implemented into a full vehicle model in ADAMS/Car and the influence to the vertical vehicle dynamics is investigated. The reference is a standard spline model.

Numerical integration of multi-body dynamics employing control constraints. **Mahmud Quasem** (Universität Siegen, Germany), Peter Betsch (Universität Siegen, Germany), Stefan Uhlar (Universität Siegen, Germany) GA/CT3341/001

The present work deals with the control of underactuated multibody systems. Our approach is based on the use of servo (or control) constraints (see, for example, [1]) which are incorporated into the underlying rotationless formulation of multibody dynamics [2]. In this connection we focus on the stable numerical integration of the resulting set of differential-algebraic equations. In particular, we aim at an energy-consistent integrator which facilitates the algorithmic conservation of angular (and linear) momentum.

Energy-momentum conserving integration of parallel manipulators. **Stefan Uhlar** (Universität Siegen, Germany), Peter Betsch (Universität Siegen, Germany) GA/CT2405/001

In the framework of a rotationless formulation for multibody systems, we present an investigation of spatial multibody mechanisms. The benefit of this kind of formulation is the design of energy-momentum conserving integration schemes, which facilitate a stable numerical integration of differential algebraic equations governing the motion for open-loop and closed-loop systems.

We introduce a coordinate augmenation technique for the incorporation of rotational degrees of freedom and subsequently perform a size-reduction to lower the computational costs and to improve numerical conditioning. In this connection a new approach to the systematic design of discrete null space matri-

ces for closed-loop systems is presented [1]. Furthermore the treatment of nonholonomic constraints is addressed.

A nonlinear finite-element framework for flexible multibody dynamics. **Nicolas Sänger** (Universität Siegen, Germany), Peter Betsch (Universität Siegen, Germany) GA/CT2457/001

We present a uniform treatment of rigid-body dynamics and nonlinear structural dynamics. The advocated approach is based on a rotationless formulation of rigid bodies, nonlinear beams and shells. In this connection, the specific kinematic assumptions are taken into account by the explicit incorporation of holonomic constraints. This approach facilitates the straightforward extension to flexible multibody dynamics by including additional constraints due to the interconnection of rigid and flexible bodies. We further address the design of energy-momentum schemes for the stable numerical integration of the underlying finite-dimensional Hamiltonian systems.

To demonstrate the superior numerical performance of the proposed methodology, the numerical examples deal with closed-loop multibody systems containing both rigid and flexible bodies undergoing large deformations.

Symbolic simplification of equations of multibody dynamics in VSD software. **Dmitry Vlasenko** (Universität Magdeburg, Germany), Roland Kasper (Universität Magdeburg, Germany) GA/CT3031/001

This paper introduces a new preprocessing method for the symbolic simplification of equations of motion of mechanical systems. The integration of the method in the component-oriented simulation tool VSD (Virtual System Designer) greatly improves the numerical efficiency of the software.

Due to the fact that the simulation of multibodies in VSD is performed in a strictly component-oriented way, mechanical submodels can be modelled, tested and compiled independently from each other. The tool is based on a non-iterative algorithm that is applicable to mechanisms with any joint type and any topology, including branches and kinematic loops. The simulation of big good-partitioned systems has complexity O(N), where N is the total number of simulating bodies.

The most time-expensive routines of the simulation process in VSD are the calculation of accelerations and the post-stabilization of constraints, which need the finding of roots of matrix equations. Accounting the sparsity of matrices the routineŠs numerical efficiency can be significantly improved. That is why we developed a preprocessing module in Maple software which performs the symbolic simplification of the QR decomposition and the complete orthogonal decomposition of matrices.

The use of the preprocessing module has the following advantages:

1. Sparse structure of matrices is used completely without any run time overhead.

2. The numerical operations with numerical elements of matrices are performed already during the translation.

3. Additional operations with arrays of indexes (like in usual sparse solvers) are not needed.

Tests show that the integration of the preprocessing module in VSD significantly reduces the computation cost of the simulation of multibodies.

A quasi-static approach for constrained systems in real-time simulation. **Bernhard Burgermeister** (Universität Halle–Wittenberg, Germany) GA/CT3551/001

The rapidly increasing complexity of multi-body system models in applications like vehicle dynamics, robotics and biomechanics requires qualitative new solution methods to slash computing times for the dynamical simulation.

Detailed multi-body systems are designed for accurate off-line simulation. For real-time applications simplified models are used. The presented quasi-static solution method focuses on accelerated computation of the low frequency parts of the solution of the nonlinear equations of motion. The high frequency parts are eliminated by neglecting some of the inertia forces and torques. This reduces numerical stiffness and allows larger step-sizes for the time-integration.

The efficient and real-time capable combination with existing highly efficient algorithms for multi-body dynamics ($\mathcal{O}(N)$ multi-body formalisms) requires appropriate integration methods that are adapted to the special structure of the multi-body formalism and solve the non-linear constraints with a small, limited number of calculation steps.

Work done in collaboration with M. Arnold (Martin–Luther–University Halle–Wittenberg, Germany) and A. Eichberger (INTEC GmbH, Wessling, Germany)

Simulation of constrained mechanical systems. **Panagiotis Koutsovasilis** (TU Dresden, Germany), Michael Beitelschmidt (TU Dresden, Germany) GA/CT3470/001

Motion equations of dynamic constrained mechanical multibody systems (MBS) are described by differential and algebraic equations (DAE). Various methods for simulating DAEs using commercial DAE-solvers are implemented. A comparison study concerning the quality of their results is presented. Issues, such as the importance of DAE-index, finding a consistent set of initial conditions, the drift-off phenomenon as well as the application of projection and stabilization techniques are discussed.

Keywords: DAE, constrained mechanical systems, index, comparison study.

GA/CTS4892/01: Friction, sliding, stiction.

To the rolling contact in multibody-systems. **Felix Fritz** (Universität Karlsruhe, Germany), Wolfgang Seemann (Universität Karlsruhe, Germany), Daniel Wilde (Universität Karlsruhe, Germany) GA/CT1192/001

Rolling motion in multibody-systems is often described by pure rolling with holonomic constraints. For a realistic motion however, it is necessary to know in which way lubrication and friction affect the rolling. Particularly due to lubrication, motion may change from pure rolling to sliding.

For the simulation of multibody dynamics, reduced models for contact stress and resulting forces are of interest. Therefore different models for normal and tangential forces in lubricated

rolling contact were examined. Due to limited simulation time general contact formulations could not be applied. Therefore specific contact models for rolling geometries (for example balls) have been implemented into Fortran environment.

A multi-body system with two-dimensional contact interface. **Stamm Wolfgang** (LuK GmbH & Co. oHG, Germany) GA/CT3130/001

In the present talk we introduce a multi body system of rigid bodies with 2D frictional surface-to-surface contacts. The problem of multiple contacts between rigid bodies is addressed within a regularization approach derived from the classic PRANDTL and REUSS model of time-independent plasticity. Analogous to common practice in continuum mechanics, discretization is done for the two-dimensional contact interface. The model incorporates sliding and sticking states of the contact. Friction properties, such as Stribeck curves, can be represented locally in this framework.

The proposed method is suitable for mechanical systems which can be treated as rigid bodies but need to include motions caused by the distribution of frictional forces in the contact region. As a technical example, investigations of a vehicle's clutch system are presented. The self-centering effect of two rotating disks contacting each other with a misalignment is examined.

Straight chain of interconnected mass points under the action of non-symmetric dry friction. **Igor Zeidis** (TU Ilmenau, Germany), Klaus Zimmermann (TU Ilmenau, Germany), Mikhail Pivovarov (TU Ilmenau, Germany) GA/CT1899/001

In [1], the motion of a linear oscillator under the action of a small non-symmetric Coulomb dry friction force is discussed. Here, we consider the motion of a chain of n interconnected equal material points with masses m placed on a rough straight line and connected by equal kinematical constraints $l(t)$. It is supposed that the system undergoes a small non-symmetric Coulomb dry frictional force $\varepsilon m F(\dot{x})$, $\varepsilon \ll 1$ acting from the surface contact with the ground on each mass point and opposite to the direction of motion. The magnitude of this force also depends on the direction of motion: $F(\dot{x}) = F_+$, if $\dot{x} > 0$, $F(\dot{x}) = F_-$, if $\dot{x} < 0$, $F(\dot{x}) = F_0$, if $\dot{x} = 0$, $-F_- < F_0 < F_+$, $F_- \geq F_+ \geq 0$. An averaging procedure is applied to the equation of motion. For $n \leq 5$ an explicit expression for the stationary "on the average" velocity V of the motion of the system as a single whole is found. For $n > 5$ an algebraic equation for the corresponding stationary velocity of the motion of the system is obtained. A dependence of stationary velocity on the number of mass points n in a chain and value of asymmetry $\mu = F_+/F_-$ is found. It is shown that the magnitude of the velocity of the chain increases with the increasing number of mass points n. This dependence is monotonous individually for even and not-even n. The obtained theoretical results can be used for the design of worm-like vibration robots.

Stability analysis of the linear non-conservative systems with fractional damping. **Vladimir Kobelev** (Universität Siegen, Germany) GA/CT1409/001

In considering design problems for non-conservative systems the integral structural characteristics as fundamental frequencies, critical loads for instability and the sensitivity analysis plays an important part. In this lecture, the influence of small perturbation on a linear, non-conservative dynamical system exhibiting a flutter type bifurcation has been investigated. The methods for dynamical instability are applied to study the eigenvalue problem for governing equations with fractional derivatives, i.e. for a special class of pseudodifferential equations. The hereditary damping is described by means of fractional derivatives. To study the dynamical instability for non-conservative governing equations with fractional damping the method of auxiliary eigenvalue problem is applied. The stability conditions of generalized Lyapunov type for the system with hereditary damping were derived. Because the solution of damped one degree of freedom oscillator could not be represented in terms of exponent functions, the stability conditions for non-conservative systems with fractional damping are essentially of generalized Lyapunov type. Namely, the solution of the fractionally damped oscillator deliver two-parametrical Mittag-Leffler functions. The behaviour of Mittag-Leffler functions is similar to those of the trigonometrical functions of complex argument; thus, the vibration of fractionally damped oscillator is somewhat analogous to the vibration of common viscous oscillator by small damping. The modal decomposition of fractionally damped system with several degrees of freedom allows to establish the stability conditions in terms of the eigenvalues of the generalized eigenvalue problem.

The numerical analysis of the influence of the blankholder force and the friction coefficient on the value of the drawing force. **Paweł Kałduński** (Koszalin University of Technology, Poland), Leon Kukielka (Koszalin University of Technology, Poland) GA/CT3081/001

On this paper the numerical analysis of the drawing process with the blankholder is presented. The influence of the value of the blankholder force on the value of the drawing force is examined. A different friction coefficients of the sheet metal for die and blankholder is considered. A defect at the lack of the blankholder is presented. The analysis in the system LS-DYNA is passed. The material model with the consolidation power, isotropic and isothermal is used. Technological parameters of the sheet-metal to drawing, the die, the stamp and the blankholder from the literatures are chosen. Sample results of computer simulations with stress distributions in a disk is presented.

The numerical analysis and experimental research of influence of triangular Asperity's outline deviations, after turning on the burnished product's technological quality. **Agnieszka Kulakowska** (Koszalin University of Technology, Poland), Leon Kukielka (Koszalin University of Technology, Poland) GA/CT2733/001

The paper concerns determination dependence of preparing inaccuracy surface texture after previous treatment on the state and properties of burnished article's surface layer (SL). The researches were realized in two stages, in the first one numerical analyses were made, and in the second one experimental verification of receiving results. The application in ANSYS was elaborated. It makes possible to analyze the influence of outline deviations triangular asperity after turning on the surface roughness, the state of strains and stresses in SL after burnishing rolling. The variables in calculations are: height deviation of triangular asperity after turning $\Delta h_t = 0.01 \div 0.04$[mm], and its spacing deviation $\Delta s_t = 0.05 \div 0.2$[mm] as well as the depth of burnishing $g = 0.03 \div 0.39$[mm]. The calculations for the case of burnishing the triangular asperities with vertical angle $\theta = 120°$, from steel45 were introduced as an example. The simulation's results were used to elaborate the one parameter functions of regress. The essential influence of asperity's outline deviations after turning on the technological quality of burnished product was showed. The numerical analyses results were experimental verified. There were turned the regular asperities with triangular outline on the surfaces of cylindrical samples from steel45. The samples were characterizing

by the variable height deviation of neighboring asperities in range $\Delta h_t = 0 \div 0.05$ [mm]. Next the samples were burnished and the measurements of parameters of roughness R_a, R_z, R_t, $R_s m$ and Wt were executed. The one parameter graph of dependence of height's deviation after burnishing from height's deviation of asperity after turning, for three depths of burnishing, was prepared. The results of experimental researches and numerical analyses cover in 5% confidence interval.

Anwendung eines Schmerzsensors. **Frank Schiefer** (TU Braunschweig, Germany), Georg Ostermeyer (TU Braunschweig, Germany) GA/CT1523/001

Die Erforschung von Schmerz aus technischer Sicht ist ein bisher wenig behandeltes Forschungsgebiet. Ein erster Ansatz zur Problembeschreibung ist in [1] gegeben.
Die weitere Grundlage zur Anwendung eines Schmerzsensors ist ein Sensorkonzept zur Schmerzdetektierung [2,3], mit dessen Hilfe ein Energieeintrag gemessen wird, der als ein Schmerzmaß für technische Systeme infolge periodischer und stoß artiger mechanischer Beanspruchungen interpretiert werden kann. Dieses entwickelte Schmerzmaß enthält implizit u. a. frequenzselektive Informationen über das Zeitverhalten des Energieeintrages sowie über die Ruckbeanspruchung dynamischer Systeme.
Anhand eines einfachen Demonstrators, der beispielsweise ein Gehmaschinenbein oder einen Roboterarm darstellt, wird gezeigt, wie die Bahnplanung einer Bewegung hinsichtlich des Schmerzmaßes optimiert werden kann. Die so entwickelte schmerzoptimale Bahn wird darüber hinaus mit weiteren Optimalitäts-
kriterien der Bahnplanung verglichen. Im einzelnen werden schmerzoptimale Bahnen des Demonstrators beispielsweise mit weg-, zeit- und energieoptimalen Bahnen verglichen.

Real-time FEM for haptic applications under consideration of human perception. **Gerhard Schillhuber** (TU München, Germany), Heinz Ulbrich (TU München, Germany) GA/CT2282/001

This work addresses the fast computation of contact forces for haptic applications using the finite element method. In general, a human operator interactively manipulates an object with a haptic input device. With the provided force feedback it is possible to display the occurring contact forces to the human operator. Typical applications include haptic simulations such as surgery simulators, robotics and force prediction in telepresence scenarios. To guarantee a realistic force feedback, accurate models need to be generated. The objects are modeled using the finite element method (FEM), such that deformable bodies can be taken into account. The drawback of a fine discretization is the high computation time for a certain contact and deformation state. In contrast, the FEM computation has to be performed within a several milliseconds to provide a continuous force feedback signal to the human. An analysis of the human perception of continuous force signals is presented. The results are integrated in a new iterative solution method for the FEM problem. Considering human perception reduces the number of evaluations, because the force changes, which are undetectable by the human, do not have to be computed. The dynamics of the multibody system are evaluated by using a time integration method. So various physical effects can be treated such as soft contact, friction and inertia. Simulation results are presented to show the capacity of the algorithm.

Continuous workspace analysis for parallel cable-driven Stewart–Gough platforms. **Tobias Bruckmann** (Universität Duisburg–Essen, Germany), Dieter Schramm (Universität Duisburg-Essen, Germany), Manfred Hiller (Universität Duisburg–Essen, Germany) GA/CT1834/001

Parallel cable-driven Stewart–Gough platforms consist of a movable end-effector which is connected to a machine frame by motor driven cables. Since cables can transmit only tension forces, at least $m = n + 1$ cables are needed to tense a system having N degrees-of-freedom. This results in a kinematical redundancy and gives $m - n$ degrees-of-freedom in the cable force distribution.

For this reason, the workspace analysis is complex and very time-consuming. Therefore, reliable and robust algorithms are demanded to calculate the resulting workspace for a given parameter set (cable winch positions and platform connection points). To analyze the workspace, discrete methods are widely used. However, the drawback of these methods is that intermediate points on the discrete calculation grids are neglected. Especially for parallel mechanisms, this may lead to false results and thus be dangerous. A promising way to avoid this kind of discretization problems may be by analyzing the workspace by so-called interval arithmetics. This contribution provides the basic ideas of a continuous workspace analysis for cable-driven Stewart-Gough platforms. The results of the interval analysis are illustrated for some geometric parameter sets. Noteworthy, the presented algorithms yield guaranteed workspaces and are usable for both the completely restrained systems ($m = n + 1$) as well as for the more difficult redundantly restrained systems ($m > n + 1$).

For practical application (e.g., in robotics), parameter synthesis to generate particular workspace geometries is mandatory. However, in general the resulting workspace gemomtries are very complex and not intuitive to the design engineer. Here, the extension of the analysis methods to methods usable for the synthesis is shown and presented along with an illustrative example.

New development of parallel robots and micro-robots with three, four and five degrees of freedom. **Doina Liana Pisla** (Universitatea Tehnicã Cluj-Napoca, Romania), Anneline Vidrean (Technical University Cluj-Napoca, Romania), Nicolae Plitea (Universitatea Tehnicã Cluj-Napoca, Romania), Adrian Pisla (Technical University Cluj-Napoca, Romania), Calin Vaida (Universitatea Tehnicã Cluj-Napoca, Romania) GA/CT2968/001

All over the world it can be noticed that the product miniaturisation is a central theme in product development for different application areas.

In robotics scientific research one of the most important approaches is concerning the raise of the positioning accuracy by the use of parallel structures. The progress of the industrial production, especially the development of the industrial robotics is more and more based on a new generation of robots

based on closed kinematic chains mechanisms, the parallel robots.

The parallel kinematic structures have a series of advantages that makes them proper for micro-robots building: the actuators positioned on the seating, actuators separation from the workspace, miniaturization capabilities, stiffness, high positioning precision and repeatability.

In the paper are presented some variants of parallel robots and micro-robots with three, four and five degrees of freedom, which are used for manipulation within the high precision assembling processes. For the parallel micro-robots were developed the geometric virtual models by using the Solid Edge virtual modeling software packages. The modeled solutions are developed with classical joints and with pseudo-elastic joints.

The corresponding kinematic models have been developed from some geometric models.

Experiments in non-smooth mechanics with a passive-actuated robotic arm. **Tobias Welge-Lüssen** (ETH Zürich, Switzerland), Christoph Glocker (ETH Zürich, Switzerland) GA/CT3039/001

Since every technical system has to deal with friction and impacts (e.g., bedstops due to a limited workspace) the motivation for examining such systems as non-smooth systems on a theoretical level is quite high. The proposed non-smooth mechanical system consists of a passive-actuated robotic arm, which has the shape of a 2-link serial manipulator and will be used as an experimental platform for the verification of control strategies for non-smooth mechanical systems.

In order to describe the different aspects of the model and the experimental behavior of the passive-actuated manipulator, the overall model and the result of various experiments performed on it will be presented.

The model takes the non-smooth behavior of the dynamics due to impacts and friction into account and incorporates the flexible properties of the physical structure, especially of both arms and of the shafts within the joints connecting two arms. In addition the electrically powered elements (motor respectively brake) and the measuring devices are included in the model.

Besides experiments for the identification of the system-parameters and the validation of the measuring devices, results for open-loop paths of precalculated time optimal trajectories will be shown and compared to the results based on a time-stepping simulation of the system.

A modified reliable distance algorithm for octree-encoded objects. **Cornelius Grimm** (Universität Duisburg-Essen, Germany), Eva Dyllong (Universität Duisburg-Essen, Germany) GA/CT3124/001

Among other approaches, such as implicit surfaces, constructive solid geometry or boundary representations, octrees feature a powerfull technique for the geometric modeling of rigid objects. A multi body system can be modeled with a composition of octrees for an efficient collision detection or collision prevention applications.

In this paper, we provide an algorithm for a reliable distance calculation of octree encoded objects. The algorithm is based on previous algorithms of Dyllong and Luther and has running times that are considerably shorter in different case scenarios, particularly in the worst case scenario.

Theory and experiments for distant effects in impacts. **Christoph Glocker** (ETH Zürich, Switzerland), Ueli Aeberhard (ETH Zürich, Switzerland), Matthias Payr (ETH Zürich, Switzerland) GA/CT1608/001

The paper addresses the question of non-localizable constitutive laws in Lagrangian impact dynamics. By setting up the kinematic, kinetic and energetic consistency conditions for frictionless multi-impact configurations, a set of admissible post-impact velocities is identified which generalizes the concept of perfect unilateral constraints to impulsive motion. Based on this set, impacts are classified with respect to their topology, intensity and dissipation behavior. Of particular importance for this classification is Moreau's half-line of local impact effects, which meets on its end the point of maximal dissipation. To address impacts with distant effects which are events apart from this line, Fremond's approach of setting up a matrix of restitution coefficients is carried out by a proper parameterization of the admissible post-impact velocity set. After having treated the scleronomic case, the theory is extended to configurations with uniform and non-uniform kinematic excitation, followed by a discussion of problems arising in systems with kinetic excitation. Measurements have been performed on Newton's cradle with three up to five balls, but also on longitudinal bars to experimentally validate the concept of prefect unilateral impulsive constraints, in particular in view of distant effects. For the evaluation of the experimental data, a mass-orthogonal decomposition of the impact in the spirit of constrained motion in classical mechanics has been performed. It decomposes the impact into impact-invariant directions with generalized momentum conservation and into directions which may be affected by the impact event.

On the Euler-Maupertuis principle of least action. **Remco Leine** (ETH Zürich, Switzerland), Ueli Aeberhard (ETH Zürich, Switzerland) GA/CT2109/001

Usually, Hamilton's Principle is used to derive the Lagrange's equations of motion (or vice versa), which yield second-order differential equations in time t and allow us to obtain the temporal solution curve $\mathbf{r}(t) = \begin{bmatrix} x(t) & y(t) \end{bmatrix}^{\mathrm{T}}$ for a mass m in a (2D) potential field. Starting from Hamilton's Principle, the current paper discusses how we can derive the Euler-Maupertuis Principle of Least Action (abbr. PLA)

$$\sqrt{2m}\int_{x_0}^{x_1}\sqrt{E-V(x,y)}\sqrt{1+y'(x)^2}dx = \text{stationary}, \qquad E = T+V = \text{const.}$$

which is sometimes called the Principle of Jacobi. This variational principle allows us to *directly* obtain the space curve $y(x)$ of the mass m in the potential field $V(x,y)$ without referring to the temporal dynamics. Alternatively, the PLA can be used for the inverse problem: find a robot/machine which realises a certain spatial curve $y(x)$ of its end-effector. The PLA dates back to Euler and Maupertuis and is the ancestor of Hamilton's Principle. Although the PLA is well known in theoretical physics, it seems to be almost forgotten in analytical dynamics. The aim of the paper is threefold. First, a historical overview of the PLA is given and its relation with Fermat's Principle is explained. Secondly, the use of the PLA in analytical dynamics is shown and the principle is applied to the looping curve of constant normal reaction. Thirdly, the PLA is put in the context of non-smooth dynamics, giving the principle a novel application field.

A parameterisation of impact laws in perfect multi-contact collisions. **Ueli Aeberhard** (ETH Zürich, Switzerland), Christoph Glocker (ETH Zürich, Switzerland) GA/CT2202/001

Impacts in rigid multibody systems cause instantaneous jumps in the generalised velocities. Naturally, the velocity after impact depends on the chosen impact law. An impact law should fulfil kinematic, kinetic as well as energy restrictions. In this paper, we study the domain of possible post-impact velocities for *arbitrary* impact laws. For single-contact collisions, this domain is at most one-dimensional but the domain becomes higher dimensional in the multi-contact case. The domain of possible post-impact velocities is a compact convex subset of the tangent space to the configuration manifold. Using a complete canonical parameterisation, the post-impact velocity of all impact laws can be addressed. For instance, the impact law corresponding to maximal dissipation as well as Newtons (extended) impact law are examples of incomplete canonical parameterisations. These impact laws are not complete as non-local impact effects are not addressed. Here, we try to find a complete canonical parameterisation which covers non-local impact effects. Moreover, the relationship between symmetries and conservation laws in this context will be elucidated.

Hammering in gear wheels. **Peter Eberhard** (Universität Stuttgart, Germany), Pascal Ziegler (Universität Stuttgart, Germany) GA/CT3977/001

The dynamic behavior of gear trains in Diesel engines is very often accompanied by a rattling motion of teeth within the backlash, called gear hammering. It originates in a transmitted mean torque that is small compared to dynamic loads introduced by gas forces, for example. Therefore the flanks are likely to lift off and reestablish impact-like contacts on both sides of the flanks causing a hammering noise. Clearly, the precise knowledge of these contact forces is very important for gear design. Typically, in industrial practise rigid body models are used to simulate these contacts, even though they have been developed for the investigation of sliding contact instead of impacts. Furthermore, since in gear trains the gears are often thin to reduce inertia, the compliance of the gear body influences the contact behavior significantly. Contact investigations of gears using transient finite element models reveal that in fact the gear body compliance may strongly influence the contact behavior and that dynamic gear body effects must be considered for precise simulations of contact forces. Since rigid body body models can not account for such effects and finite element models can only be used for some few impacts due to the huge numerical effort, a modal approach is proposed, where the gear wheel dynamics is described in a modally reduced formulation using a moving frame of reference. In combination with collision detection and a local force law, this approach allows very precise investigations of contact problems. Moreover, since all necessary data is determined in preanalyses, the integration is numerically extremely efficient. To validate this approach, experiments of test bodies impacting teeth of real gears have been carried out and compared to simulation results and a very good agreement is observed. Therefore, this approach offers a validated and precise contact model that is numerically efficient enough to be incorporated into overall engine models.

Impacts on 1D structures. **Roland Zander** (TU München, Germany), Heinz Ulbrich (TU München, Germany) GA/CT2865/001

Instancing the Woodpecker toy, which is a classic example for non-smooth mechanical behaviour, a description for the two and three-dimensional behaviour of slender elastic structures in presence of colliding bodies is developed. A special focus is laid on the discretisation of the elasticity, where different approaches can yield different advantages: the classical approach within flexible multibody systems (MBS) are global shape functions describing the deformation of the entire structure with respect to the discrete degrees of freedom. This gives a well defined limitation of the frequencies described within the model but is – in contrast to FE-approaches – insufficient to describe locally bounded effects like impacts on the structure. Here the FEM gives a locally bounded description.

The effect of modelling the flexibility of structures with impacts then is studied on the model of the Woodpecker toy: the rod representing the trunk is modelled as rigid followed by elastic models allowing for two and three-dimensional dynamics. In case of the elastic model, the Woodpeckers oscillation changes due to the interference with the structures oscillation. This structural vibration is induced and highly influenced by the Woodpeckers movements which continuously change the boundary conditions one the structure. This can be interpreted as changing mass distribution on the structure. When using a rigid model for the rod this effect is not included in the model.

This academic example of the woodpecker toy is presented since it holds all effects of interest for non-smooth dynamics of MBS: smooth mechanical parts, impacts and structural elasticities. At the same time it is simple enough to allow for judging the results obtained based on everyday experience. The methods and models described here can be used for the simulation of drive-trains, continuous variable transmissions (CVTs) and other machine parts.

02, Minisymposia

GA/MP396/002: Mechanical properties of biomembranes.

Organiser: Matthias Röger (MPI Leipzig, Germany)
Co-organiser: Rumiana Dimova (Max Planck Institute of Colloids and Interfaces, Germany)

Cell membranes constitute a basic structure of biological systems and have been a focus of scientific research over the years. Their complex architecture and the variety of processes involved explain the vitality of the subject as well as the difficulties that emerge in their analysis. A combined effort from different disciplines is often necessary to achieve a better understanding. In this minisymposium we will focus on a very few specific aspects with contributions both from biophysics and mathematical analysis.

Lipids and other amphiphilic molecules self-assemble into thin bilayers, which are the building blocks for many components of living systems. These five nanometer thick bilayers build the walls of cells and other cellular organelles. Under normal circumstances, lipid bilayers and biomembranes are not rigid but rather flexible and, thus, undergo thermally excited shape fluctuations such as protrusion modes or bending undulations. The latter give rise to a variety of shape transformation in vesicles.

Membranes within biological systems interact with many macromolecules. For example, on the inner surface, the plasma membrane is attached to networks of relatively stiff filaments which are part of the cytoskeleton inside the cell. A model system for these complex interactions is provided by systems containing lipid bilayers and polymers. Thus, the interaction of membranes with various molecules and particles has been addressed in theoretical analysis and simulations.

Even the fundamental processes in simple model systems pose an interesting challenge for a mathematical analysis. The self-assembling of lipid molecules into thin surface-like structures sharing both a solid-like and a fluid-like character is one example. Phase separation processes coupling the shape of a membrane to diffusion or coarsening on their surface is another one.

Phase separation in biomembranes: a diffuse interface approach. **Axel Voigt** (FZ caesar, Germany) GA/MT4021/002

Biological membranes form the interface between cells and its environment. They are a mixture of many different types of lipidic and protein components, and their relative amounts and composition differ between functionally distinct domains and changes dynamically during such processes as movement, division and vesicle trafficking. The local curvature has been recognized as a key parameter that might be related to precise biological properties. Various mechanism have been identified, which can generate positive or negative curvature, among these are: a) changes in lipid concentration, b) cytosceletal assemly and c) scaffolding by proteins. Even if all desired molecular informations were available, the computer time required to describe these interactions would be totally prohibitive.

A mathematical description which links microscopic morphology and biological function, thus should have the curvature as a key ingredient. Most studies on continuum models in this direction have been concerned with equilibrium shapes. Dynamic models are much more involved as they require a complex coupling between surface evolution, lipid composition and protein diffusion, which leads to highly nonlinear partial differential equations on evolving surfaces. The solution of such problems requires special care on the discretization and its theory is much less developed than for problems on Cartesian grids.

We develop for a thermodynamically consistent model for multicomponent lipid membranes a diffuse interface approximation which circumvents these technical difficulties and in addition allows to deal with topological changes.

Visualizing the dynamics of soft matter: membranes, nano-particles and vesicle fusion. **Julian Shillcock** (Max Planck Institute of Colloids and Interfaces, Germany) IC/MT4109/002

Biological membranes have properties and behaviour that emerge from the propagation across many scales of the molecular characteristics of their constituents. Artificial smart materials, such as drug delivery vehicles and biosensors, often rely on modifying naturally-occurring soft matter, such as polymers and lipid vesicles, so that they possess useful behaviour. Mesoscopic simulations allow in silico experiments to be easily and cheaply performed on complex, soft materials requiring as input only the molecular structure of the constituents at a coarse-grained level. Additionally, mesoscopic simulations provide the only currently feasible window on the length and time scales relevant to important biophysical processes such as vesicle fusion. We present recent work using Dissipative Particle Dynamics (DPD) simulations to explore the structure and behaviour of amphiphilic membranes, the fusion of vesicles, and the interactions between rigid nanoparticles and soft surfaces.

Membrane deformation under polymer pressure. **Carlos Marques** (CNRS-Institut Charles Sadron, France) GA/MT4077/002

Polymers and membranes are the one and the two-dimensional archetypes of the soft objects that compose the colloidal world. Ubiquitous in the living realm and in many industry formulations, these fluctuating ropes and sheets display a fascinating behaviour that has inspired many developments at the forefront of present nanotechnology trends. Soft Condensed Matter objects such as those made from polymers and membranes are easily deformed by viscous, electric, magnetic or gravitational forces. They also exhibit thermal fluctuations. This susceptibility to weak forces provides many pathways for structuring and patterning a range of nanostructures from soft materials Here I will present recent theoretical and experimental progress in the understanding of membrane behaviour under polymer stress.

I will first show theoretically what forces are expected when a polymer and a membrane are brought into interaction range, and compute the deformation of the membrane under polymer pressure. I will then present recent experimental progress from systems of phospholipid giant vesicles spread on a DNA carpet.

A mesoscopic model for cell membranes. **Matthias Röger** (MPI Leipzig, Germany) GA/MT4050/002

We derive a mesoscopic model for membranes formed by amphiphilic molecules. Such molecules consists of a polar *head* and a non-polar *tail* and self-assemble into surface-like structures. Starting from a microscopic description we obtain an energy defined on densities of head- and tail-groups. A mathematical analysis shows that this *mesocsale-energy* reflects the basic mechanical properties of cell membranes and is connected to a classical bending energies.

This is work done in collaboration with Mark A. Peletier (University of Technology, Eindhoven).

Large-scale simulation of arterial walls: mechanical modeling. **Dominik Brands** (Universität Duisburg-Essen, Germany), Jörg Schröder (Universität Duisburg-Essen, Germany), Daniel Balzani (Universität Duisburg-Essen, Germany), Axel Klawonn (Universität Duisburg-Essen, Germany), Oliver Rheinbach (Universität Duisburg-Essen, Germany) GA/CT1840/002

Biological soft tissues appearing in arterial walls are characterized by a nearly incompressible, anisotropic hyperelastic material behavior in the physiological range of deformations. For the representation of such materials we apply a polyconvex strain energy function, cf. [1], in order to ensure the existence of minimizers [2] and in order to satisfy the Legendre-Hadamard condition automatically. To account for the anisotropy the concept of structural tensors and representation theorems for anisotropic tensor functions are used and the energy is formulated in terms of the principle and mixed invariants of the deformation and structural tensor.

When arteries are overstretched, discontinuous damage is observed. For the modeling of this effect we apply a damage model specified in [3], which basically assumes that the damage occurs mainly in fiber direction. For the numerical simulation we consider an atherosclerotic artery and apply a high internal pressure which is comparable to the pressure applied during a balloon-angioplasty.

The 3D-discretization results in a large system of equations, therefore, a parallel algorithm using FETI-DP is applied to solve the equilibrium problem. The details of the domain decomposition method applied to this problem are discussed in a talk by O. Rheinbach.

Discussion on appropriate material parameters for a porous media model of the IVD. **Nils Karajan** (Universität Stuttgart, Germany), Wolfgang Ehlers (Universität Stuttgart, Germany), Bernd Markert (Universität Stuttgart, Germany) GA/CT3992/002

In general, the intervertebral disc is known to be a representative of charged hydrated soft tissues, thereby exhibiting several coupled dissipative effects resulting from distinct swelling properties, interstitial fluid flow as well as an intrinsic viscoelastic extracellular matrix. Furthermore, its unique structure is dominated by embedded collagen fibers yielding a very efficient load bearing mechanism. In the past, it has been proved that a model based on the Theory of Porous Media (TPM) comprises a very efficient treatment of all the necessary characteristics which can be merged in a modular manner. However, regarding experiments on tissue specimens, it is often not possible to separate the involved effects as it is the case for the theoretical model. Hence, one of the main problems is the identification of the theoretically introduced material parameters. Moreover, the model includes certain structural properties, such as the fiber orientation or the fixed charges density, which are inhomogeneously distributed over the tissue. They can often be easily observed, and integrated into the model, but the relevance of these inhomogeneities to certain deformation modes of the IVD remains unknown. The goal of this contribution is to quantify the above mentioned problems and to discuss the possibilities for a reasonable parameter identification as well as a judgment of their influences.

Simulations of hydrated media with implicit Dirichlet boundary conditions. **Ayhan Acartürk** (Universität Stuttgart, Germany), Wolfgang Ehlers (Universität Stuttgart, Germany), Bernd Markert (Universität Stuttgart, Germany) GA/CT3978/002

Charged hydrated porous media, which are found in biomechanics as well as in geomechanics, have the capability to change their volume under varying chemical conditions of the environment. In this contribution these materials are modelled in the framework of the thermodynamically consistent Theory of Porous Media (TPM). The advantage of such a continuum mechanical model is that neither the porous micro structure nor the geometrical distribution of the constituents must be known.

The model underlying consists of four constituents, a charged solid and an aqueous solution composed of water and the ions of dissolved salt. The solid is modelled by a finite elasticity law accounting for the multiphasic micro structure, whereas the fluid is considered as a viscous *Newton*ian fluid. One finally ends up with four balance relations, the volume balance of the fluid, the concentration balance of the cations, the momentum balance and the balance of charges of the overall mixture.

The resulting set of partial differential equations is solved within the framework of the FEM. Therefore, the weak forms are derived and the resulting set of equations for the primary variables pore pressure p, cation concentration c and solid displacement $\mathbf{u}_S$, is implemented into the FE tool PANDAS. Finally, a three dimensional example is shown.

Material stability aspects for viscoelastic collagen fibers. **Bernd Markert** (Universität Stuttgart, Germany) GA/CT4009/002

The continuum mechanical modeling and predictive simulation of fibrous biological tissues, such as tendons, ligaments, skin etc., is of common interest in the field of computational biomechanics. In this regard, various strain-energies have been proposed to capture the inherent anisotropy caused by the aligned collagen fibers ranging from simple exponential functions to more sophisticated formulations based on the theory of invariants (see quotations in [1]) which are well established in macroscopic models of arterial walls and spinal discs.

The specific goal of this contribution is to describe the apparent relaxation and creep response of type I collagen fibers under tension which is believed to result from subfibrillar slippage mechanisms, whereas the elastic properties are brought into connection with the flexible regions in the collagen D-period [2]. Therefore, proceeding from a general polynomial-type strain-energy function formulated in the fiber stretch [1], the multiplicative geometric concept of finite solid viscoelasticity is applied in the framework of thermodynamics with internal state variables. In particular, the strain energy and thus, the stress are constitutively split into equilibrium and non-equilibrium parts governing the elastic and the rate-dependent fiber response. The evolution of the inelastic fiber deforma-

tion is thereby described by a thermodynamically consistent rate equation (viscoelastic flow rule) which remains valid even for large perturbations away from thermodynamic equilibrium. Moreover, the concise formulation still meets the requirements of a stress-free reference state and material stability, whereas the number of material parameters is kept to a minimum.

A multiphase theory for the description of remodeling and growth in anisotropic living tissues. **Tim Ricken** (Universität Duisburg-Essen, Germany) GA/CT2337/002

The continuous capability of soft and hard living tissue to optimize their inner structure and material properties by growth, remodeling and morphogenesis is currently under study by groups of mechanic, biology, medicine and chemistry. Although a wide knowledge regarding the mechanisms being involved has been improved, it came out that these phenomena are extensively complex and of multi-scale dimension. A common approach is to assume that the tissue reacts to either stress, strain or even the rate of one of these effects. Models based on these assumptions may lead to good results, e.g. strain which induces bone remodeling or stress inducing remodeling and growth of soft tissue. Nevertheless, it is beyond dispute, that in addition to the stress or strain state, there are additional mechanisms which affect the remodeling and growth of biological tissues, e.g. growth factors or other dissolved solutes in the non-viscous fluid and the solid matrix. Due to the fact that tissue is composed of several components, in this contribution a multi-phase theory will be presented. The growth and remodeling mechanism is treated using a coupled description where several phases are involved. In order to formulate thermodynamic consistent restrictions, a closed system approach is being used. As a direct consequence, the validity of the mixture mass balance can be guaranteed without the introduction of a surface mass flux. Under consideration of the additional information captured by the coupled multiphase description, a new approach for the phenomena of growth and remodeling will be discussed. After presenting the developed framework for the calculation concept which is describing a growth in anisotropic biological tissues, some representative numerical examples are being examined.

Deformation of bilayer lipid membranes in bio-inspired materials and systems. **Raffaella De Vita** (Virginia Tech, USA) GA/CT4363/002

Bilayer lipid membranes (BLMs) have been successfully used in numerous medical, defense, and engineering applications such as drug delivery systems, sensors for detecting biological agents, and photovoltaic cells. Despite the fact that BLMs offer great promise for many applications, only few experimental investigations have been conducted to characterize their mechanics. Performing mechanical experiments is very challenging due to the poor stability and nanometer size thickness of BLMs. Therefore, the formulation of mathematical models becomes crucial not only in understanding the mechanical behavior of these lipid assemblies but also in guiding the design of suitable experiments.

A mathematical model will be presented to describe the deformation of planar BLMs that constitute many bio-inspired materials and systems. The BLM is assumed to be a Smectic A liquid crystal. Thus, the mean orientation of the amphiphilic molecules comprising the BLM is postulated to be perpendicular to the layers. Each layer is idealized as a two dimensional liquid. The small deflections of simply supported BLMs subjected to pressure loads that act perpendicularly to the layers are studied. The equilibrium equations and boundary conditions are derived from the bulk elastic energy proposed by de Gennes and Prost (1993) by using variational methods. The solution of the fourth-order differential equation for the resulting boundary value problem is found analytically by using cylindrical functions and their mathematical properties. *Work done in collaboration with Iain W. Stewart.*

Modeling the cerebral blood flow using a multiscale finite-volume approach. **Johannes Reichold** (ETH Zürich, Switzerland), Alfred Buck (Universitätspital Zürich, Switzerland), Bruno Weber (Inst for Pharmacology and Toxicology, Universit, Switzerland), Patrick Jenny (ETH Zürich, Switzerland) GA/CT1956/002

Cerebral blood flow (CBF) can be defined as the rate of delivery of arterial (nutritive) blood to the capillary beds of a particular mass of brain tissue. CBF assumes a fundamental role in homeostasis and neural activity as it regulates the supply of glucose and oxygen.

A multiscale finite volume method is employed to model CBF in a realistic vascular network. High-resolution 3D data of the cerebral angioarchitecture in animal models acquired by Weber et al. [1] are utilized. The imaged blood vessels are divided into groups of large, medium and small lumen. While large and medium vessels are fully resolved, the capillary bed is modeled as an isotropic grid. Pressure is assumed to be constant in the large vessels while it may vary for smaller sizes. Other vessel properties such as diameter and curvature are represented by a corresponding transmissibility value.

Vasodilation during neural activity or partial occlusion in cerebrovascular impairment are examples of localized changes in vessel attributes. It is investigated how these local alterations affect the global CBF. Among others, insights gained from the simulations are valuable for the correct interpretation of data acquired by magnetic resonance imaging modalities. In addition, the validity of the description of blood as a Newtonian fluid is tested for various conditions.

Dynamics of blood flow in the Willis circle using a quemada mode. **Adrian Postelnicu** (Universitatea Transilvania din Brasov, Romania) GA/CT3376/002

The Willis polygon (or Willis circle) is an arterial system, located at the base of the brain, which represents a security biological device. The paper presents new results on the dynamics of blood flow in the Willis circle, by taking into account the non-Newtonian nature of the blood through a Quemada model [3]. In previous papers [1-2] we performed a steady analysis of the blood flow in the Willis polygon, by considering the blood as a Newtonian fluid. In hemodynamics this is the first step, while taking into account the non-Newtonian behaviour of the fluid is called a second order approach. This is in fact the aim of our paper, to compare the results (blood flow rates and pressures) obtained in a non-Newtonian approach with those furnished by a Newtonian modeling of the blood.

This model is embedded in a standard analysis of a complex network of pipes, which is in fact the Willis circle from the hemodynamics point of view, by using a Quemada non-Newtonian model, as presented in [4]. Flow-rates in the arteries and pressures in their junctions are obtained and are compared with those corresponding to the Newtonian case. Then, in a second step, we extend our analysis to the unsteady flow in the Willis circle.

Novel method of pulse wave diagnostics based on compression of a superficial artery. **Natalya Kizilova** (Kharkov Polytechnic University, Ukraine) GA/CT389/002

Wave propagation in the arteries is widely investigated in application to medical diagnostics. Determination of the diagnostically important parameters and their biomechanical interpretation are connected with mathematical approach to data analysis and solution of the corresponding coupled problem for the blood flow and vessel wall movement. Some novel aspects of the wave propagation in the arteries are connected with wave separation into their forward and backward running components, wave-intensity analysis, analysis of the resonant harmonics and the pressure-flow P(U) curves. Pulse wave propagation and reflection in a series connection of a viscoelastic tube and two complex resistances is considered as a model of the intraorgen arterial vasculature. Expression for the input admittance of the system taking into account wave reflection at the end of the tube is obtained. The dependence of the input admittance on the geometrical and mechanical parameters of the system is investigated. The equation for calculation the harmonics at which the input admittance reaches its extreme is obtained. The harmonics is considered as resonant, when any alteration in terminal admittance causes significant variation in the amplitude. The influence of variations of the model parameters within the physiological range on the amplitude and the phase spectra of the input admittance is investigated. The outer compression of the artery during the pulse palpation procedure is modeled as non-uniform pressure distribution at the outer surface of the tube. The parameters of the pressure wave (the modulus and phases of different harmonics) at the inlet of the system contain all possible information on the state (normal or pathological) of the inner organs. It is shown that at a proper slight or deep compression some harmonics may be amplified while the others are attenuated. Based on the theory of the so-called resonant harmonics of different inner organs the novel method of pulse wave palpation is proposed. The results are compared to other methods like separation of the pressure wave into its forward and backward components, estimation of the parameters of the reflected wave and wave-intensity analysis.

The modelling and dynamic analysis of flow through the aortic valve during the cardiac cycle. **Krzysztof Patralski** (Wroclaw University of Technology, Poland), Piotr Konderla (Wroclaw University of Technology, Poland) GA/CT4208/002

In mechanical terms the human heart is a kind of pump. During pulsation, the heart pumps blood around the body trough the circulatory system. The direction of blood flows and the mode of blood inflow into the ventricles are controlled by four valves which act as non-return valves. The object under study is an aortic valve, located in the aortic annulus. The main goal of this study is to consider the dynamic function of the model that consists of the aortic valve and the aortic artery wall model. Simulation is assumed to reflect the natural conditions of the flow through the valve. The earlier studies are presented[1,2].

The valve is composed of three spherical cusps connected to the common ring. Each leaflet is built of three layers. The aortic artery wall model is characterized by comosite structure. This objects are treated as the three symmetry plane objects. We assumed the hiperelastic Mooney–Rivlin material model. Fluid is assumed as incompressible Newtonian model. The dynamic density coefficient η = const. The load is variable in time.

The analysis problem is solved numerically by using FEM[3]. The computations were performed using the Ansys Multiphysics system. The fluid–structure interaction process is modelled using ALE method (Arbitrary Lagrange Euler).

A sensitivity analysis of the Hill muscle model with respect to gait dynamics. **Daniel Strobach** (Universität Duisburg–Essen, Germany), Andres Kecskemethy (Universität Duisburg–Essen, Germany) GA/CT2232/002

This paper analyzes and quantifies the sensitivity of the Hill-type actuator model with respect to its characteristic parameters. It focuses on the influence of parameter variations in the context of forward dynamics simulations of muskuloskeletal motor tasks. The analysis is performed using a simplified subsystem of the human leg consisting of pelvis, thigh shank and foot, interconnected by planar joints at hip, knee and ankle. The system comprises one antagonistic muscle pair at the

knee for knee flexion and extension (*vastus intermedius* and *biceps femoris caput brevis*). The activation of muscle is modeled using a simplified parameterization based on smooth profile patches. To simulate the swing phase of gait, rheonomic constraints are imposed on pelvis (translation and rotation), hip (rotation) and ankle (rotation). The paper shows that the different parameters involved in the muscle model can have significant varying influence on the resulting behaviour, showing which parameters need to be determined accurately and which allow for a more rough estimation.

A comparison of static optimization criteria for resolving the muscle-redundancy problem during human gait. **Ye Ou** (Universität Duisburg–Essen, Germany), Andres Kecskemethy (Universität Duisburg–Essen, Germany) GA/CT2273/002

In human movement, several muscles activate a single degree of freedom, leading to the problem of force redundancy. To resolve this, static optimization offers a computational advantage, while neglecting dynamic effects. However, such static optimization techniques often render suitable results, and are thus frequently found in biomechanics literature. In this paper, we investigate different approaches of static optimization for predicting the muscle forces. A four-segment linked leg musculoskeletal model with motion in the sagittal plane is considered. The joint moments generated by muscles are computed from inverse dynamics. The muscle force is estimated by different optimization criteria, each satisfying the moment constraints at all joints and the minimum and maximum muscle force constraints. Several criteria described in literature are studied using linear or nonlinear optimization. The results obtained from these calculations are compared with each other.

Reduced kinematic model of the human spine for biomechanic application. **Christian Simonidis** (GAMM, Germany), Wolfgang Seemann (Universität Karlsruhe, Germany), Manuel Scharmacher (Karlsruhe, Germany) GA/CT2418/002

Based on functional anatomy a detailed kinematic model of the human spine is developed. The human spine is an agile and adaptive mechanical system consisting of several biological components such as bones, ligaments and muscles. Thus it can be seen as a highly kinematic and dynamic coupled multibody structure, where the bones can be considered as rigid body elements. Intervertebral discs and facet joints form a defined relative motion range between two adjacent bodies. Ligaments as well as muscles couple the whole structure. The present kinematic coupled model has three degrees of freedom and represents the motion range of the biological system. Further, we define a substitutional joint for relative kinematics between vertebra prominens and pelvis allowing a motion range close to the motion range of a human torso. Results are verify by mapping motion capture data from motion study on the models.

Anatomically-based mechanical models of the human pelvic floor. **Leo Cheng** (University of Auckland, New Zealand), Kim Noakes (University of Auckland, New Zealand), Andrew Pullan (University of Auckland, New Zealand), Ian Bissett (University of Auckland, New Zealand) GA/CT4391/002

There are gaps in our understanding of the role of different muscles in the pelvic floor region and their relative contributions to maintaining continence and the normal defecation process. To address this deficiency, we have created anatomically realistic finite element (FE) models of the structures within the pelvic floor region.

The FE models were constructed from images of male and female cadavers from the Visible Human Project and MRI data from a normal live female subject. For each data set, up to 14 individual structures of interest were manually segmented from the axial images. Segmented points were then reviewed again against saggital and coronal images and also reviewed by an anatomist and a pelvic floor surgeon. FE representations of each of the structures were created using a non-linear fitting procedure that minimised the orthogonal distance between segmented points and the FE mesh to produce an RMS error of less than 1.1 mm.

A 'bear down' or abdominal squeeze was simulated on the levator ani (LA) muscle of the live subject by solving the governing finite elasticity equations. The LA muscle was represented by a 160 node FE mesh with tricubic Hermite interpolation and an isotropic two parameter Mooney-Rivlin material law. Boundary conditions were applied to represent the in vivo conditions. Nodes at the posterior of the LA muscle that corresponded to points attached to the coccyx bone had all displacements fixed and nodes that corresponded to the portions attached to the fasciae of the obturator internus muscles were constrained to move only the superior-inferior direction. A pressure of 4 kPa (corresponding to an average supine intra-abdominal pressure during valsalva) was applied to the superior surface of the LA muscle and the resulting deformation computed. The simulated data was correlated against a dynamic, saggital MR image obtained from the same subject during the valsalva manoeuvre.

Study of human body stability under the vertical vibration action into an autovehicle using Laplace transforms. **Mariana Arghir** (Universitatea Tehnicã Cluj-Napoca, Romania), Simona Rodean (Universitatea Tehnicã Cluj-Napoca, Romania) GA/CT1155/002

We present a study for imagining of generalized mechanical model for the human body / seat assembly. The model will by used for the dynamics analyze of the human body constituent parts, under the vertical vibrations influence, transmitted by the vehicle seat during its displacement. Measures of the dynamic responses of the body are represented by the transfer functions. The human body can be considered as a mechanical system and it may be roughly approximated by a linear lumped parameter at low frequencies (less than $100\,\mathrm{Hz}$) and low vibration levels. The resonance phenomenon appears due of the interaction of the concentrated masses with the pure elastically structure. This model is needed to investigate the human response to vibrations. The mechanical model of human body is defined in terms of discrete masses, dampers and springs.

Under the vibration action, the human body multiplies or diminishes the vibrations magnitude in accordance with mechanical vibration laws, as a mechanical system with mass, elasticity and damping characteristics. This is a mechanical model of the human sits upright on the seat cushion on the seat and consists of four parts: pelvis, upper torso, viscera and head. Therefore, the model has 5 DOFs in translation, where 4 DOFs represent the human body constituent parts and 1 DOF is for the seat cushion. Applying Laplace Transforms, the motion

differential equations system writing in time domain becomes an equivalent algebraic system in frequency domain, which is frequency response function of system and is expressed by the $H(s)$ transfer matrix and them transfer functions. Stability of the human body is established using the found poles. The human body motion laws with four independent coordinates are given in a graphical representation.

Bridging scales: an attempt to incorporate cellular responses within a 3D FEM model of active muscle contraction. **Oliver Röhrle** (University of Auckland, New Zealand), John Davidson (University of Auckland, New Zealand), Juliana Kim (University of Auckland, New Zealand), Andrew Pullan (University of Auckland, New Zealand) GA/CT1373/002

Mathematical models representing skeletal muscles as 3D objects are rare. Most of them describe the contractile mechanics of skeletal muscles using the Finite Element method (FEM) to discretise the governing equations of finite elasticity and incorporating transversely isotropic constitutive laws, which mimic basic physiological properties of passive and active muscle mechanics.

Such models, however, are not capable of investigating the mechanical response of a muscle with respect to recruitment patterns, spatially varying contractions, or fatigue. To do so, it is essential to incorporate information from the cellular level. The challenge is thus to bridge and link information obtained from different scales specifically from the cellular level to the biomechanical FEM muscle model.

A mathematical model of the cellular responses of skeletal muscles has been integrated within a 3D biomechanical FEM model. For each muscle fibre, the skeletal cell model is able to reproduce a number of cellular properties including the action potentials of the sarcolemma and T-tubule, Ca^{2+} concentrations, and fatigue responses. The FEM model is based on a cubic Hermite Finite Element discretisation of the governing equations of finite elasticity theory and a transversely isotropic constitutive law.

To incorporate the cellular information into the FEM model, homogenised values of key physiological parameters, e.g. the calcium concentrations, are computed at Gauss points. These values are then used to modify the stress tensor in such a way that it resembles its contractile response. The methodology is applied to simulate the mechanical response of the semitendinosus after a nerve stimulus initiates muscle contraction.

The advantages of such an improved 3D FEM model are far reaching. These models can be used, for example, to investigate and study local muscle contraction, muscle recruitment patterns, force generation, or fatigue response of skeletal muscles.

Estimation of material properties of cancellous bone using multiscale FEM. **Sandra Ilic** (Ruhr-Universität Bochum, Germany), Klaus Hackl (Ruhr-Universität Bochum, Germany), Robert Gilbert (University of Delaware, USA) GA/CT2338/002

Cancellous bone is a spongy type of bone with voids filled by blood marrow. Without much loss of generality it can be modelled as a material with periodic microstructure where overall parameters can be calculated using some homogenization method. Here the multiscale finite element method is applied and the assumed representative volume element (RVE) is a cube with solid frame and fluid core. From the point of view of the finite element method the RVE is a combination of solid and shell elements with two types of boundary conditions. On the fluid-solid interface continuity of displacements orthogonal to this surface is required and as a consequence of the Hill-Mandel macrohomogeneity condition on the external boundary of the RVE periodic boundary conditions must be satisfied. We would like to consider acoustic excitation so that a complex stiffness matrix and complex displacements appear in the solution of the problem. Calculation of overall properties is repeated for different geometries of the solid frame.

Bearing of geometric and material properties to bone strength in bending. **Werner Winter** (Universität Erlangen–Nürnberg, Germany) GA/CT1841/002

Osteoporosis is characterized by decreasing of bone mass and bone strength with advanced age. For characterization of material properties of bone the volumetric bone mineral density (vBMD) is one of the most important contributing factors to bone strength. Often bending tests of whole bone are used to get information about the state of osteoporosis. From an uniaxial test of a bone specimen it is assumed that an elastic region exists up to initial yield stress and a following hardening region. In bending tests beside material properties geometric properties like shape and cortical thickness appropriate the non-linear load-deformation curves.

In a first step, different types of cellular structures are considered to characterize vBMD and its influence to elastic and plastic material properties. By scaling of the vBMD with the density of dense bone a relative volumetric bone mineral density can be regarded. Afterwards, the classical theory of plastic bending is used to describe the non-linear moment-curvature relation of a whole bone. For bending of bone with sandwich structure an effective moment of inertia can be defined. The shape factor as a pure geometrical value is considered to define bone strength due to bending in the non-linear range. This factor is discussed for a bone with circular cross section and different thickness of cortical bone. The deduced relations and the decrease of material properties are used to demonstrate the influence of osteoporosis to bone bending strength.

It can be shown that the elastic and plastic material properties of cellular bone are related to a relative volumetric bone mineral density. Starting from an elastic-plastic bone behavior with an constant yield stress the non-linear moment-curvature relation in bending is related to yielding of the fibres in the cross section. The ultimate moment is characterized by a shape factor depending on the geometry of a cross section.

About the necessity of extended remodeling theories in bone adaptation. **Tobias Ebinger** (Universität des Saarlandes, Germany), Stefan Diebels (Universität des Saarlandes, Germany), Holger Steeb (Universität des Saarlandes, Germany), Thorsten Tjardes (University Witten/Herdecke, Germany) GA/CT1706/002

At the moment an optimization process in the surgery of femoral neck fractures can be observed. While in former years mainly the complete head of the femur was replaced by an implant, now there is the trend to save the head if possible and to fixate it at the femur by screws. Thereby, numerical simulations provide the possibility of optimizing the position of the screws or of predicting failure under certain loading conditions.

Due to the complex microstructure of spongy bone (trabecular microstructure) deformation modes of higher order appear

leading to size effects. These higher order (e. g. bending-like) modes can not be reflected by standard continuum theories. Thus, continuum models considering higher order effects may be used to include such effects. However, that raises the question, if the extra effort is really needed, because the higher order deformation modes may avail failure, or – if unnecessary – it is blowing up the numerical cost only.

On the basis of a three dimensional anisotropic model for bone remodeling the need of extended biomechanical continuum models predicting failure is discussed.

Computation of statistically-equivalent load sets for bone-remodelling simulation. **André Lutz** (Universität Hannover, Germany) GA/CT2150/002

Theories and related computational techniques for the prediction of bone mass loss, for example caused by endoprosthetic treatment, are under discussion since more than 20 years. Today numerical aspects and constitutive modelling of stress adaptive bone remodelling seems to be solved sufficiently, but an open question arises from the description of the loading conditions in the framework of quasi-static approaches. Due to the complexity of the subject there is only a small data base available on measured and computed joint and muscle forces for typical movement situations. To close this gap an inverse simulation approach on the identification of statical equivalent load sets, related to measured bone mass density distributions, will be presented in this contribution. Based on a first order approach of bone remodelling, these load sets are computed by an hierarchical genetic-gradient algorithm and lead to the original bone mass distribution obtained by high resolution imaging techniques. Under consideration of these biomechanically equilibrated finite element models, computational results on the bone remodelling prediction due to treatment of artificial hip-joint replacement will be presented.

A fully variational strong discontinuity approach at finite strains. **Radan Radulovic** (Ruhr-Universität Bochum, Germany), Jörn Mosler (Ruhr-Universität Bochum, Germany) GA/CT2212/003

A novel, fully variational three-dimensional finite element formulation for the modeling of locally embedded strong discontinuities at finite strains is presented. The proposed numerical model is based on the Enhanced Assumed Strain concept with an additive decomposition of the displacement gradient into a conforming and an enhanced part. The discontinuous component of the displacement field which is associated with the failure in the modeled structure is isolated in the enhanced part of the deformation gradient. In contrast to previous works, a variational constitutive update is used. The internal variables are determined by minimizing a pseudo-elastic potential. The advantages of such a formulation are well known, e.g. the tangent stiffness matrix is symmetric, standard optimization algorithms can be applied and it represents a natural fundament for error estimation and mesh adaption.

Finite-element formulations of shear localization in granular materials. **Tuyet Trinh** (Ruhr-Universität Bochum, Germany), Klaus Hackl (Ruhr-Universität Bochum, Germany) GA/CT3662/003

Displacement and mixed finite element formulations of shear localization in granular materials are presented. The formulations are based on hypoplastic constitutive laws for soils and the mixed-enhanced treatment involving displacement, strain and stress rates as independently varied fields. Included in these formulations are the standard displacement method, the three-field mixed formulation, the method of incompatible modes, the enhanced assumed strain method and the mixed enhanced strain method. Several numerical examples demonstrating the capability and performance of the different finite element formulations are presented. The numerical results are compared with available experimental data of Hostun RF sand and numerical results of Karlsruhe sand on biaxial tests.

Crack propagation calculation using trial cracks. **Martin Bäker** (TU Braunschweig, Germany) GA/CT1906/003

We present a method to perform finite element calculations for crack propagation problems with arbitrary crack directions in two dimensions. The crack direction (angle of propagation) is determined by inserting small “trial cracks” at the crack tip. For each trial crack, the domain is remeshed to allow crack propagation between elements. The trial cracks are then opened and the energy release rate is measured. The optimum crack direction (i.e., the crack direction with maximum energy release) is determined by an optimisation procedure. Although the method is computationally expensive due to the need to perform several calculations for each crack increment, it has the advantage that the energy release rate can be calculated even in cases where other methods fail. After explaining the method, it is applied to several test examples comparing it to other methods.

Creep damage anisotropy of thin-walled element structures. **Vyacheslav Burlayenko** (National Technical University ’Kharkov Polytechnic, Ukraine) GA/CT838/003

The talk is devoted to damage-induced due to a creep anisotropy (transversally-isotropic) of metallic materials under thermo-mechanical loading. Both types of an initially isotropic and anisotropic material were considered. For the description of initial anisotropy and damage-induced anisotropy the second-order damage tensor has been used. Constitutive equations are based on irreversible thermodynamics, namely the Helmholtz free energy. Theoretical results were compared with experimental data; the results of comparison were satisfactory. The proposed model was generalized to describe damage anisotropy (transversally-isotropic) and lifetime prediction in thin-walled elements of structures, using the engineering models of plates and shallow shells. The method of numerical simulation of an anisotropic creep damage analysis on the basis of finite element scheme was elaborated. Various creep properties of damage-induced anisotropy plates depending on the orientation of anisotropy axes of a material concerning to a direction of loading and from a degree initial anisotropy have been established.

Non-isothermal creep-damage model of heat-resistant steel. **Gennadiy Lvov** (Kharkov Polytechnic University, Ukraine), Evgen Kostenko (Dr.-Ing. Siemens AG Steam Turbine Technology, Germany) GA/CT773/003

Constructional elements of gas and steam turbines function in conditions of the high temperatures and complex loadings for a long time. Creep-damage analysis and determination of rupture time are the important part of turbine design. Numerous results of transient thermal analysis for high and low pressure turbine casing, exhaust casing and diffusers specify non-uniform character of distribution of temperatures that demands of non-isothermal creep and damage analysis. The purpose of this paper is to develop improved theory for heat-resistant steel and computer methods for calculate high temperature creep and damage of turbine components. Constitutional equations for ratio creep deformations and the kinetic equation of damage accumulation with continuous functional dependence on temperature are offered. For uniaxial stress behavior under constant stress and temperature the theoretical creep curves have first, second and tertiary stages. The technique of parameters verification for uniform model is developed on the basis of experimental creep curves and long-time strength in a wide range of temperature changes. Identification of the parameters in the non-isothermal creep-damage model, for one type of heat-resistant steel used in the turbine industry, is carried out. For numerical calculations of complex components of turbines the software is created, enabling using the developed model in FEM - program complexes. Calculations of creep are carried out and time rupture is found for elements of steam and gas turbines with use of various ways of the account of temperature change.

Fatigue life investigation using non-destructive testing methods. **Zoran Stankovic** (Ruhr-Universität Bochum, Germany), Otto Bruhns (Ruhr-Universität Bochum, Germany) GA/CT2186/003

Experimental investigation of the fatigue life prediction of two different specimen forms made from steel 42CrMo4 is described. The fatigue load was defined as a cyclic loading with constant and non constant amplitudes in tension range and with different stress ratios. This loading range leads to a high cyclic fatigue behaviour of both specimens. During the test, the growth of the fatigue crack was monitored using two different non-destructive methods, namely acoustic emission and the electric resistance. Acoustic emission was used for detecting sound waves as a result of dissipation of elastic energy during micro cracks and cracks growth, as well as for the detection of the place of crack initiation. Electric resistance was used for the monitoring and quantitative investigation of the crack growth.

On the effect of Kirkendall voids on solder-joint reliability. **Kerstin Weinberg** (TU Berlin, Germany), Thomas Böhme (TU Berlin, Germany), Wolfgang Müller (TU Berlin, Germany) GA/CT2515/003

Microelectronic circuit boards consist of the Si-chip itself and its packaging, which includes wiring and solder joints between different metal layers. Failure of these joints is a well established cause of failure of the whole circuit board. In addition to the challenges posed by the replacement of lead in solder joints the miniaturisation of microelectronic components is changing the failure mode of interest from conventional thermal cycling induced fatigue to drop impact induced solder joint fracture. Experimental evidence shows that the formation and growth of so-called Kirkendall voids significantly contributes to the degradation of solder joint strength and drop reliability.

For a continuum mechanical approach to such processes the question is: How can the additional information about the micro-structural development be included in a constitutive model? One possibility is the use of a general mesoscopic concept, firstly introduced by Muschik and his co-workers (see [1] and cited works) to describe a certain microstructure with continuum mechanical methods. The basic idea is the extension of the space-time domain by a set of mesoscopic variables. Additionally, a mesoscopic distribution function is introduced; in this way a statistical element enters the classical continuum theory.

By means of this mesoscopic theory we model a general viscoplastic solid material with a certain porosity. In this way it is possible to link the mechanisms of chemo-mechanical induced growth of voids to parameters which describe the macroscopic material softening. Numerical simulations provide inside into the (not yet completely understood) mechanisms of failure by formation and growth of Kirkendall voids.

Identification of material symmetry for anisotropic damage evolution due to a growing mixed-mode crack. **Kianoush Molla-Abbasi** (Ruhr-Universität Bochum, Germany), Henning Schütte (Ruhr-Universität Bochum, Germany) GA/CT2209/003

A numerical study of a growing mixed-mode internal elliptical/circular crack in a unit cell was undertaken with the help of a finite element simulation. The model enables us to measure the components of the elastic compliance/stiffness tensor of the unit cell related to the principle loading axes as the crack grows. With this the evolution of the type of material symmetries and the evolution of the anisotropic damage are resulting.

The matrix of the unit cell is considered to be linearly elastic, homogenous and isotropic and the crack is small compared to the unit cell, so that the non-interacting crack assumption for damage models is fulfilled and the overall behavior of the unit cell is linearly elastic. This enables us to use linear elastic fracture mechanics (LEFM) concepts for the propagation of the microcrack.

The propagation of the crack is governed by the principle of maximum driving force which is a direct consequence of the variational principle of a cracked body in equilibrium and considers the effect of all three stress intensity factors. Without any ad hoc assumption, the crack growth rate is calculated using its thermodynamic duality with the local maximum driving force.

As the crack propagates, remeshing algorithm deletes the mesh, extends the crack and meshes the unit cell according to the new crack configuration. For each propagation step the components of the compliance tensor are calculated with the help of 6 basic deformation modes at which the unit-cell is either under pure shear or under pure tension. It is observed that the symmetry of the unit cell at each step of crack propagation is approximately orthotropic.

The impact of different fracture criteria on the evolution of the damage and the crack tip parameters are compared and the advantages of the maximum driving force criterion are discussed.

Keywords: anisotropic damage, compliance tensor, crack propagation, material symmetry

The effect of crack faces contact interaction on the critical strain in composites under compressive loading. **Bartlomiej Winiarski** (University of Aberdeen, UK), Igor Guz (University of Aberdeen, UK) GA/CT1188/003

Nowadays many primary structures in aviation and aerospace [1] applications are made of layered composite materials [2]. Components made of composite laminates due to their internal structure and manufacturing methods often contain a number of inter- and intra-component defects which size, dispersion and mutual interaction alter significantly the critical compression strain level [3]. The current study investigates the effect of the cracks interaction and crack faces contact interaction on the critical strain in laminar transversally isotropic material (cross-ply) compressed in a static manner along interlaminar defects. The frictionless Hertzian contact is considered for the interacting crack faces.

The statement of the problem is based on the most accurate approach, the model of piecewise-homogenous medium [4] and the 3-D stability theory. The moment of stability loss in the microstructure of material is treated as the onset of the fracture process. The complex non-classical fracture mechanics problem is solved utilizing the finite elements analysis. The results are obtained for the typical dispositions of cracks. It was found that the crack faces contact interaction alter significantly the critical strain level of the composite.

Simulation of skin-stiffener debonding in stiffened curved carbon/epoxy panels. **Claudio Balzani** (Universität Karlsruhe (TH), Germany), Werner Wagner (Universität Karlsruhe, Germany) GA/CT1725/003

In the last decades, fiber-reinforced materials have obtained huge attention for high performance lightweight structures. Especially in the aircraft industry carbon/epoxy laminates play an important role due to their low weight paired with high stiffness and strength. But still there is a need for reliable and robust simulation tools in the design phase which incorporate evolutionary damage growth. One damage scenario which reduces significantly the load-carrying capacity of fuselage structures is the separation of the skin from the stiffeners. The aim of this presentation is the numerical treatment of this damage scenario in multi-directional carbon/epoxy panels in the framework of the finite element method. For this purpose, the composite itself is modelled with layered quadrilateral shell elements of Reissner-Mindlin type. For the description of skin-stiffener debonding isoparametric cohesive interface elements are derived. A cohesive law based on publications of de-Andrés et al. [1999] and Ortiz & Pandolfi [1999] is edited in a way that only tensile normal tractions trigger damage. Furthermore, the cohesive free energy function is enhanced by an additional penalty term in order to avoid the inter-penetration of the crack faces. Some numerical examples with experimental evidence demonstrate the applicability and the performance of the proposed model.

Material dispersion in dynamic deformation process of solids under impact action. **Adam Glema** (Poznan University of Technology, Poland) GA/CT3632/010

The dispersion as the solid material property is discussed in the paper. The phenomenon is well known from the point of view of wave analysis and is one of the main criteria for wave classification. Nevertheless mechanics of solids is still the branch of research and construction of mechanical and civil engineering structures, where dispersion and wave analysis play the minor role in process of conception, design, verification and production. The definition, origination and dispersion analysis in solids are presented. In the paper we concentrate on the mechanical behavior of solids. Wave nature, rate dependent material respond is the result of dynamic impact loading. The mechanical problem of inelastic deformation of solids is considered. The evolution of deformation under impact loading is described by rate dependent, hardening and softening viscoplastic model of material. The dispersion phenomenon is studied to introduce the adequate material model for the advanced states of deformation processes. The evolution problem is formulated within the frame of theory of thermodynamics and viscoplasticity. Mathematical analysis for elastic, plastic and viscoplastic material evidence the non-dispersive or dispersive property. Occurrence of dispersion in the analysis problem has the consequences not only for constitutive relation. It influences the whole problem with advantages in formulation and solution. Numerical results of example problems present qualitatively different mechanical response for materials with different dispersion. The formation of finite strain localization zone is controlled by viscous material parameters. Wave character and dispersion are recognized as fundamental elements in formulation and solution in dynamic processes with strain localization and shear band propagation. Physical and numerical aspects of dispersion clarify the development of deformation, stress or energy distribution and verify solution procedure. The dispersive character of material in analysis of plastic strain localization is essential and non neglectable phenomenon within solid mechanics problems.

Modeling of tear propagation in soft hydrated biological tissue. **Hans-Uwe Rempler** (Universität Stuttgart, Germany), Wolfgang Ehlers (Universität Stuttgart, Germany) GA/CT4020/002

Similar to dense solid materials, soft tissues tear due to strain overloading. However, the damage behavior (i.e., the tear expansion and propagation), also depends on the hydration of the tissue and may be affected by the interstitial fluid flow.

In this contribution, soft biological tissues are modeled using the Theory of Porous Media (TPM) which allows the description of multi-component continua with internal interaction. Here, the tissue is described by a standard two-phase model consisting of a solid matrix and an interstitial fluid. For the numerical treatment of the tearing mechanism, an extension of the Finite Element Method (X-FEM) is applied. In order to account for the increased fluid percolation in the opening tear, a special treatment of the permeability characteristics is required.

Within this framework, the influence of the pore-fluid flow on the tear propagation is examined in canoncial numerical examples.

Numerical analysis of chip formation during machining for different values of failure strain. **Jaroslaw Chodor** (Koszalin University of Technology, Poland), Leon Kukielka (Koszalin University of Technology, Poland) GA/CT2895/003

Machining is a very complicated technological process. To better understand the process of chip formation and various phenomena that can occur, we need to know what happens during machining. Separating material from base is one of the most important factors to be analysed, where the maximum value of failure strain is overflow. This value presents the stiffness of material after exceeding a particular limit, beyond which cracking and dividing of the material is observed. In the literature, this value typically falls within the range $\varepsilon_i = 0.25$ to 3, for various kinds of materials. Obtaining this value theoretically, and explaining its influence on the process of chip formation under experimental conditions, is a very difficult problem. Hence we proposed using some numerical analysis. Knowledge of the different values of failure strain allows observion of the critical moment within the chip-forming process, and how this value affects the state of strain and stress in the surface layer. We present results of numerical calculations for maps of strain and stress in the surface layer of actual work-pieces.

In this work attention is concentrated on chip formation and separation from the object for different values of the failure strain. The phenomena on a typical incremental step are described using a step-by-step procedure, within an updated Lagrangian formulation. Then finite element methods (FEM) and dynamic explicit methods (DEM) were used to obtain a solution. An application was developed in the ANSYS system, which makes possible a complex time analysis of the physical phenomena: states of displacements, strains and stress. Numerical computations require a proper definition of the contact zone by Single Surface Auto 2D, without the necessity to introduce boundary conditions.

The effect of fillet radius of the tool blade on the stress and strain states in the process of cutting a sheet plate with circular cutters. **Jan Bohdal** (Koszalin University of Technology, Poland), Leon Kukielka (Koszalin University of Technology, Poland) GA/CT3100/003

The influence of fillet radius of the tool blade on deformations and stresses of sheet metal in the process of cutting with numerical tools is presented. The Cowper-Symonds model is used to describe the properties of cut sheet-plate. Numerical results were obtained by the finite element method (FEM) making use of the ANSYS LS-DYNA ver. 9.0 program. The problem was approached using the central - difference method, also referred to as the explicit-integration method. It includes a few special techniques for direct integration of dynamic equations of motion.

Quasi-static crack propagation with X-FEM and material force method. **Jürgen Glaser** (TU Kaiserslautern, Germany), Paul Steinmann (TU Kaiserslautern, Germany) GA/CT2173/003

The presented work is based on the combination of two concepts being major subjects of computational fracture mechanics in recent time: The Material Force Method (MFM) and the Extended Finite Element Method (X-FEM).

The X-FEM modifies the standard Finite Element approach in order to describe the discontinuous displacement field across a crack (and the asymptotic crack-tip field) by the introduction of additional degrees of freedom (DOFs) at nodes in the vicinity of the crack. The displacement jump is modelled by a step function connected to those additional DOFs. The most obvious advantage of the X-FEM is the representation of a crack independently of the mesh such that no remeshing is needed in the case of crack propagation.

Material or configurational forces emanate from a balance law in material space which is connected to the material energy momentum tensor also called Eshelby stress tensor. The derivation of material forces is dual to the derivation of physical forces in the spatial configuration. In the case of a cracked specimen the MFM leads to a singular material force at the crack tip which is associated to a variation of the material placement of the crack tip and thus is interpreted as a driving force for crack propagation. The amount of that singular material force is equal to the J-integral of classical fracture mechanics.

Applying the MFM to FEM leads to discrete nodal material forces. The application of the Material Force Method to 2D quasi-static crack propagation within the framework of the X-FEM will be illustrated by several examples with a focus on the nodal material forces at standard degrees of freedom as a criterion for crack propagation. Examples for the geometrically linear and non-linear case will be presented and the question of how to determine the correct direction of crack propagation will be discussed.

Material force based mesh optimization in geometrically nonlinear hyper-elastostatics. **Michael Scherer** (TU Kaiserslautern, Germany), Paul Steinmann (TU Kaiserslautern, Germany) GA/CT2106/003

The aim of this work is the development of an r-adaptive scheme based on the concept of material forces. In the framework of the finite element method, the material force acting on a node of the material mesh corresponds to the gradient of the discrete potential energy with respect to the position of the node. Therefore, material forces provide the basis for r-adaptive methods that improve the finite element solution by minimizing the discrete potential energy.

The energy based mesh optimization can be considered as a minimization problem with constraints, whereas the constraints are given by the restriction that element degeneration must not occur. Based on this interpretation we developed a stable algorithm in which the distortion of the mesh is prevented by using an additional energy playing the role of a barrier function. The algorithm produces a sequence of meshes with decreasing potential energy and norm of the material node forces.

Beside the theoretical aspects and the implementation, a number of numerical experiments with triangular and tetrahedral meshes are presented. We discuss the advantage of the proposed r-adaptivity in the case of a notched and cracked specimen.

A computational framework of 3D configurational-force-driven crack propagation. **Ercan Gürses** (Universität Stuttgart, Germany), Christian Miehe (Universität Stuttgart, Germany) GA/CT4007/003

The lecture outlines a variational formulation of quasistatic brittle fracture in elastic solids and proposes a finite-element-based computational framework for propagation of cracks in three-dimensional bodies. The starting point is a variational setting of fracture mechanics that recasts a monotonic quasistatic fracture process into a sequence of incremental energy minimization problems. This extremum formulation includes the classical Griffith theory of brittle fracture. The proposed algorithm employs 4-noded linear tetrahedral elements and introduces discretized crack patterns with material-force-driven incremental nodal and crack surface releases. These releases of crack facets constitute a sequence of positive definite subproblems with successively decreasing overall stiffness, providing an extremely robust algorithmic setting in the postcritical range. The formulation is also embedded into an accompanying r-adaptive crack-pattern adjustment procedure with material-force-based indicators in conjunction with crack front constraints. The adjustment procedure allows reorientations of finite elements at the crack-front providing a considerable improvement in the predictions of *curved crack surfaces* when compared with the experimental observations. The capabilities of the proposed algorithm will be demonstrated by means of several three-dimensional crack propagation examples and comparisons with experiments.

Convergence study of crack-growth using the X-FEM. **Markus Peters** (Ruhr-Universität Bochum, Germany), Klaus Hackl (Ruhr-Universität Bochum, Germany) GA/CT1969/003

The eXtended Finite Element Method (XFEM) is a very efficient way to reduce mesh dependencies when analyzing crack growth. Displacements and stresses around the crack tip are calculated using additional shape functions which span the analytical displacement field around a crack tip.

Because of the fact that the extended shape-functions do not form a partition of unity in the transition elements, the crack path depends on

1. the number of elements used in the XFEM computation
2. the number of layers which are enriched by the crack tip functions and
3. the shape functions which are used for the standard FE

term.

We want to compare the crack-path for the crack-growth criteria (i) maximum hoop stress (ii) minimum of potential energy (iii) maximum of directional derivative of energy release using different configurations for the parameters in items 1., 2. and 3. and analyze the differences of the displacements and stresses obtained in the initial state.

Numerical determination of fatigue-crack growth in isotropic and anisotropic materials. **Markus Fulland** (Universität Paderborn, Germany), Martin Steigemann (Universität Kassel, Germany), Hans Richard (Universität Paderborn, Germany), Maria Specovius-Neugebauer (Universität Kassel, Germany) GA/CT1555/003

For the determination of fatigue crack growth in a three-dimensional structure basically two important questions do arise: Which path does the crack take? What is the crack growth rate and thus the remaining lifetime? In order to answer both questions usually the evaluation of the stress intensity factors K_I, K_{II} and K_{III} is necessary, since most 3D fracture criteria as well as the crack growth rate relations rely on those parameters. A very efficient way to numerically calculate the stress intensities on the basis of a 3D-FE-calculation is to first of all determine the energy release rates with the modified virtual crack closure integral method (MVCCI):

$$
\begin{aligned}
G_I(a,\Delta t_k)_k &= \tfrac{1}{\Delta t_k \Delta a} W_k^{\mathcal{Y}}, & W_k^{\mathcal{Y}} &= \tfrac{1}{2}\left[F_{i,k}^{\mathcal{Y}}(a)\cdot \Delta u_{i-1,k}^{\mathcal{Y}}(a)\right]\\
G_{II}(a,\Delta t_k)_k &= \tfrac{1}{\Delta t_k \Delta a} W_k^{x}, & W_k^{x} &= \tfrac{1}{2}\left[F_{i,k}^{x}(a)\cdot \Delta u_{i-1,k}^{x}(a)\right]\\
G_{III}(a,\Delta t_k)_k &= \tfrac{1}{\Delta t_k \Delta a} W_k^{z}, & W_k^{z} &= \tfrac{1}{2}\left[F_{i,k}^{z}(a)\cdot \Delta u_{i-1,k}^{z}(a)\right].
\end{aligned}
$$

The major benefit of this approach is the fact, that only non-singular fields (nodal forces $F_{i,k}$ and displacements $\Delta u_{i-1,k}$) are needed, which minimizes the mesh refinement demands. Moreover this method is applicable also for the most general anisotropic and inhomogeneous case, since no material assumptions are made in the theory. In the isotropic case the energy release rates can easily be converted to stress intensities either under the assumption of plane stress or plane strain conditions. For orthotropic materials however this conversions is much more complicated, since the energy release rates and stress intensity factors for the different fracture modes are no longer uncoupled.

In this contribution the authors will discuss the numerical issues in the process of determining fatigue crack growth in isotropic and anisotropic materials. This includes the effective calculation of energy release rates and stress intensities as well as the application of reliable 3D-fracture criteria and lifetime estimation for 3D structures. The numerical examples given in the talk will be carried out with the program system ADAPCRACK3D developed at the Institute of Applied Mechanics at Universität Paderborn.

This contribution is based on investigations of the collaborative research center SFB/TR TRR30, which is kindly supported by the DFG.

On the influence of a kink's asymptotic field on crack propagation. **Henning Schütte** (Ruhr-Universität Bochum, Germany) GA/CT3116/003

The aim is to highlight the influence of the kink developing at the beginning of mixed-mode crack growth on the propagation behavior of the crack. Le & Schuette [1],[2] have shown that the variational principle of a body containing a crack results in the principle of maximum energy release rate incorporating the stress intensity factors of the kinked crack. Here the influence of the kink and the kinking angle, resulting in a singular field around the corner, on the crack growth resistance is analyzed. The generalized stress intensity factors at the kinks corner are computed with the help of a FEM strategy. The influence of these on the plastic energy dissipated at the kink is determined using a small scale yieling approach. The impact of these results on mixed-mode crack propagation are discussed.

Thermal-shock investigation of the hybrid-forming process. **Andreas Schneidt** (Universität Paderborn, Germany), Rolf Mahnken (Universität Paderborn, Germany) GA/CT4025/003

In hybrid processes for gradient structures, inhomogeneous, cyclic thermal-mechanical stresses and strains lead to higher risks of failure of the forming die. The main topic of the presentation is the validation of the finite-element calculation for a tool-like sample under complex thermal mechanical loadings to predict the material behavior. To validate the simulated model thermal shock tests of component- or tool-like specimens of the forming die are chosen. To obtain a sufficient amount of data, optical measuring systems are used to gain data for comparison of experiment and simulation. In this way model validation can be done on the basis of shapeŰ and strain-measurements. To analyze the damage, measurements using the current eddy method are done on the surface of the cyclic-thermal-shocked test specimen. The experimental damage analyzes of the thermal-shock tests, which are executed close to reality, are necessary to receive live-time dependent data for the influence of the thermal-mechanical loadings of the hybrid deformation process of the forming die.

Non-local modeling of thermomechanical localization in metals. **Arnd Flatten** (BAM Berlin, Germany), Dietmar Klingbeil (BAM Berlin, Germany), Bob Svendsen (Universität Dortmund, Germany) GA/CT2430/003

The modeling of dynamic, high-speed loading of metallic materials, encountered for example in crash or drop tests, as well as in high-speed forming and cutting processes, involves in general a number of processes and effects such as high strain-rates, hardening behaviour, heating due to mechanical dissipation, friction and contact, thermal softening, damage, deformation localization and shear-band development. In particular, the latter process represents an instability of the original uniform deformation field due to inhomogeneous material behaviour and/or geometrical effects, resulting in extreme grain stretching over a finite, narrow domain in the structure. Rate-dependent '*local*' models according to Johnson & Cook do not generally result in a physically correct shear-band development; e.g., involving a finite, non-vanishing shear-band thickness.

In the current work, an extension of such local models is presented as based on a corresponding extension of the *rate-dependence* of the material behaviour to one on the gradient

of the accumulated inelastic deformation *rate* for high-speed processes. In particular, attention is focussed on the intrinsic length-scales incorporated via the rate-dependency of these models. On this basis, we compare and contrast local and non-local approaches in the context of their application to the modeling and simulation of dynamic, adiabatic shear-banding in the alloy Inconel 718.

Work-roll surface degradation due to spalling of the oxide layer. **Wenge Zhang** (TU München, Germany), Christian Krempaszky (TU München, Germany), Ewald Werner (TU München, Germany) GA/CT3272/003

The rolled-in scale of hot-rolled steel sheets due to the surface degradation of the work rolls often cannot be tolerated for automotive applications. In hot rolling, the degradation of the work rolls has been related to several mechanisms: thermal fatigue of the roll surface due to temperature cycles undergone by the outer layers, fatigue of the surface layers due to cyclic mechanical stresses, abrasion of the roll surface due to the contact in the roll gap and breakdown of the work-roll surface. Breakdown of small surface particles is the coming source of rolled-in-scale. This breakdown process can be considered as following: an initiation of interface decohesion between the oxide layer and substrate material due to inhomogeneous of the oxide forming process, the propagation of these decohesion (or cracks) as a sequent of micro-buckling of the oxide film and finally the occurrence of micro spalling.

In this work we analyse the damage (often caused by the oxide layer spalling) evolution to a protective oxide layer on the roll surface and investigate the role of residual stresses in the oxide layer under the cyclic thermal loading during the micro-buckling. A theoretical estimation is made of the critical stress for the micro-buckling of oxide layer. The dependence of the spalling behaviour on the temperature and thickness of the oxide layer is determined by adopting the Hutchinson-Suo bi-material model. These results are helpful to determine the optimum operating parameters for the work roll and to reduce the downtime of the rolling equipment.

On the peculiarities of a crack growth path in an anisotropic solid. **Efim Shifrin** (Russian Academy of Sciences, Moscow), Robert Goldstein (Lomonosov Moscow State University, Russian Federation) GA/CT1987/003

A linear elastic problem for a straight crack, located on a symmetry axis of an orthotropic plane is considered. It is supposed that normal loads are applied at the infinity. The strength properties of the solid are supposed isotropic. It is shown that an ideal cut is not an appropriate model for a crack when a problem of a crack growth direction is considered. In this connection an elongated elliptical hole is considered as a crack model and maximal tensile stresses as a crack growth criterion. It is shown that for some class of orthotropic materials a crack deviates from the straight path just after it starts to grow. The problem of the stability of a straight crack path under Mode I loading is considered also. It is shown that for some class of orthotropic materials a straight crack path is unstable even in the conditions of uniaxial normal tension.

Computation of stress-intensity factors in a plane homogeneous anisotropic solid. **Martin Steigemann** (Universität Kassel, Germany), Markus Fulland (Universität Paderborn, Germany), Hans Richard (Universität Paderborn, Germany), Maria Specovius-Neugebauer (Universität Kassel, Germany) GA/CT1666/003

One of the main problems in Fracture Mechanics is the propagation of cracks in solids. There are various criterions for predicting crack paths but often the stress intensity factors K play an essential role. Let Ω a bounded domain in the plane with a selvage crack. Applying an external load p, the stress intensity factors K at the crack tip can be computed with the help of special solutions to the pure homogeneous Neumann problem of 2-dimensional elasticity theory

$$\nabla \cdot \sigma(\zeta) = 0\,, \quad x \in \Omega\,, \qquad \sigma^{(n)}(\zeta) = 0\,, \quad x \in \partial\Omega\,,$$

with singular behavior near the crack tip:

$$\zeta_{1/2}(x) = r^{-1/2}\Psi_{1/2}(\varphi) + \widetilde{\zeta}_{1/2}(x), \qquad r \to 0\,.$$

Namely,

$$K_{1/2} = \int_{\partial\Omega} p(x)\zeta_{1/2}(x)\,ds$$

$r^{-1/2}\Psi_{1/2}$ are eigenfunctions of the elasticity operator and can computed exactly for an isotropic, but only numerically for an anisotropic solid. $\widetilde{\zeta}$ is a solution with finite energy of the pure Neumann problem with nonhomogeneous data. Such a solution of the Neumann problem is only determined up to a rigid body motion and a solution u exists iff the body and boundary forces are self-balanced. A weak solution u of the pure Neumann problem exists and is unique by Korn's inequality and the Lax–Milgram-Lemma in the subspace

$$H^1_R(\Omega) = \left\{ u \in H^1(\Omega) : \int_\Omega u\,dx = 0, \int_\Omega \mathrm{rot}(u)\,dx = 0 \right\}$$

with $\mathrm{rot}(u) := \partial_{x_1} u_2 - \partial_{x_2} u_1$. This unique solution can be found by applying the projection

$$P_R : \quad H^1(\Omega) \longrightarrow H^1_R(\Omega)$$

defined by

$$P_R u := u - \frac{1}{|\Omega|}\int_\Omega u\,dx + \frac{1}{2|\Omega|}\int_\Omega \mathrm{rot}(u)\,dx \left(\begin{pmatrix} x_2 \\ -x_1 \end{pmatrix} - \frac{1}{|\Omega|}\int_\Omega \begin{pmatrix} x_2 \\ -x_1 \end{pmatrix} dx \right)$$

to an arbitrary solution u of the Neumann problem. For any solid, the functions $\widetilde{\zeta}$ can only computed numerically, for example, with the finite element method. The direct Galerkin discretization of the Neumann problem leads to a linear system of equations

$$\mathbf{A}\mathbf{u} = \mathbf{f}$$

for the discrete solution $\mathbf{u}$ with a positive semi-definite stiffness matrix $\mathbf{A}$ with three-dimensional kernel. A solution only exists, iff the source term $\mathbf{f}$ is orthogonal to this kernel. With the Krylov subspace method MinRes this system of equations can be solved and gives some discrete solution $\mathbf{u}$. Applying the discrete analogon $\mathbf{P}$ of P_R, the discrete solution $\mathbf{Pu}$ is the approximation of the unique normalized solution $u \in H^1_R(\Omega)$.

In our talk we will present numerical results for isotropic and in particular anisotropic solids. On different test specimens well-known in Fracture Mechanics we will show the accuracy of the weight function method and the advantages of projections when computing the pure Neumann problem numerically.

A BE-based finite element for crack propagation processes. **Bastian Helldörfer** (Universität Erlangen–Nürnberg, Germany), Günther Kuhn (Universität Erlangen–Nürnberg, Germany) GA/CT2570/003

A boundary element based crack propagation module for finite element systems within the framework of linear elastic fracture mechanics is presented.

When dealing with the simulation of 3D fatigue crack growth a series of problems has to be resolved. The long computing time resulting from the incremental algorithm which is needed because of the nonlinear nature of crack growth must be reduced. The singular stress field in the vicinity of the crack has to be captured adequately by the simulation method. Finally, after evaluating a valid 3D crack growth criteria and determining the new crack front, the new crack geometry must be integrated into the simulation model which is still a challenging task for arbitrary 3D crack front shapes.

In this talk a combined FEM/BEM simulation is proposed to overcome the mentioned problems. While the major part of the structure is meshed with finite elements only a small domain around the crack is modelled with boundary elements. These boundary elements define a finite macro element, for which a stiffness formulation is obtained by applying the Symmetric Galerkin Boundary Element Method. While the application of the FEM reduces the computational costs all fracture mechanical investigations are treated within the BEM which is advantageously here. Since displacements and tractions are only approximated on the boundary or on the FEM/BEM interface, no additional error resulting from the discretization is made in the interior of the BE domain and hence the stress singularity along the crack front can be captured properly. Based on the interior stress field reliable fracture mechanical parameters are obtained and after evaluating a valid 3D crack growth criteria a new crack geometry is determined. When updating the simulation model, only the surface oriented, BE based finite macro element is modified which is less complicated compared to volume oriented techniques.

Examples display the benefits of the proposed simulation technique.

Bridged interface cracks under transient thermal loading. **Mikhail Perelmuter** (Russian Academy of Sciences, Moscow) GA/CT721/003

To analyze of the stress-strain state and fracture parameters of fibers reinforced composites with bridged interface cracks under transient thermal and mechanical loading the direct boundary integral equations method (DBIEM) is used. The bridged zones of cracks are considered as parts of these cracks and it is supposed that nonlinear distributed spring-like bonds with given bond deformation law link the cracks surfaces. The bonds stresses are considered as the distributed tractions applied to the cracks surfaces at the bridged zone. It is supposed that these tractions depend on the crack surfaces displacements. The bridged zones sizes and theirs evolution depend on the type and structure of the matrix and fibers materials and transient external loading. The first step of the problem analysis is the solution of the thermal problem. Time stepping convolution formulation is used for solution of transient heat conduction problems. The results of the thermal problems solution are used as the initial data for the thermal stress problems. The DBIEM formulation based on the transient quasi-static uncoupled thermoelasticity is used for thermal stress problems solution. Modeling of the bridged interface cracks is based on the multi-domain DBIEM formulation. In the frames of this approach, the DBIEM equations for each homogeneous sub-region of the structure with addition boundary conditions along the interface boundaries and along the bridged zone of crack are considered. For general case of the nonlinear bonds deformation law the iterative procedure of the solution of the DBIEM equations is used. At the first step of this procedure is supposed that the bond stiffness has a constant value along of the whole bridge zone. Some results for the structures of a finite size containing material junction of different kind and shape with variation of bridged zone size and fibers property are presented. The comparison of the DBIEM results with the results obtained previously using singular integral-differential equations (Goldstein R.V., Perelmuter M.N. Modeling of bonding at the interface crack, Internal J. of Fracture, vol. 99, N 1-2, pp.53-79, 1999) is performed. The numerical analysis of the interface crack leads to a classification of the possible regimes of the interface cracks growth in dependence on the parameters of the bond deformation law and the transient thermal loading. This research was supported by Russian Foundation for the Basic Research, the number of the grants are 05-01-00191 and 05-08-18207.

Semi-analytical modelling of cracks with interacting faces in isotropic materials under harmonic load. **Oleksandr Menshykov** (University of Aberdeen, UK), Igor Guz (University of Aberdeen, UK) GA/CT837/003

In structural materials the existing cracks often have a non-zero initial opening or a complex shape. Under the consequent dynamic loading the opposite crack faces move with respect to each other and interact. The contact interaction results in the appearance of the contact forces in the contact region and changes significantly the stress and strain distribution near the crack tips. The shape of the contact region will change in time and must be determined as a part of solution. The complexity of the problem is further compounded by the fact that the contact behaviour is very sensitive to the materials of two contacting surfaces and the type of the external loading. Such dependences make the contact problem for crack faces highly non-linear. As the consequence, in the majority of studies the interaction of crack faces was neglected and, therefore, the real stress-strain distribution was ignored due to the difficulties of finding the appropriate solution.

The present work is devoted to the investigation of the contact interaction of the faces of a crack located in the homogeneous, isotropic, linear elastic 3-D medium under harmonic loading. The Signorini contact constraints are imposed and the friction is governed by the Coulomb law.

The problem is solved by the method of the boundary integral equations with the use of the iterative procedure. The solution is refined during the iteration process until the distribution of physical values satisfy the contact constraints. The contact forces and displacement discontinuity on the crack surface are investigated for different wave parameters (frequency, direction, etc) and different values of the friction coefficient. The effect of the parameters on the stress intensity factors is studied. The results are compared with those obtained without allowance for the contact interaction. The significant difference between compared results confirms the crucial importance of taking the crack faces contact interaction into account.

04, Minisymposia

GA/MP397/004: Experimental methods in structural dynamics.

Organiser: Dieter Weichert (RWTH Aachen, Germany)
Co-organiser: Fabrice Bremand (Université de Poitiers, France)

The tremendous progress in theoretical modelling and numerical simulation in mechanics over the last decades makes it increasingly important to validate highly sophisticated simulation models by adequate and pertinent experiments in order to avoid danger to produce apparently correct results with fallacious models by pure parameter adjustment. This however requires that experiments must reach the same degree of precision as results produced by numerical simulations. As a consequence, efforts to be put into experimental equipment and design and interpretation of experiments are also increasingly high. For this reason, many researchers give up to make experiences and concentrate exclusively on theoretical and numerical work. This mini-symposium advocates experimental mechanics as a necessary and important branch of research in mechanics going beyond the up-mentioned question of validation: Very often physical effects turn out to play a dominant role in experiments, that have not been adequately considered in theoretical and numerical modelling. Therefore, experiments frequently open ways for re-thinking modelling. This mini-symposium covers only a small part of experimental mechanics. The particular area this mini-symposium focuses on is the dynamic behaviour of structures and structural elements, especially under impulsive loading. Among others, the questions addressed are how to design adequately experimental set-ups, how to apply loads in a controlled manner, how to monitor and document the evolution of significant field quantities of the considered specimen in the dynamic process.

Experimental and numerical investigation of shock wave-loaded plates. **Marcus Stoffel** (RWTH Aachen, Germany), Ruediger Schmidt (RWTH Aachen, Germany), Dieter Weichert (RWTH Aachen, Germany) GA/MT3549/004

If thin-walled structures like plates or shells have to be designed as protection against blast loadings such as explosions, numerical simulations can turn out to be very helpful means for dimensioning. The large variety of commercial finite element codes based on different mechanical models, may however lead to quite different results in numerical application. It is therefore important to develope experimental techniques allowing to examine very precisely structural deformations under shock wave-loading conditions, which may be used in the assessment of numerical models. In the present study an experimental set-up for such purposes is presented. Two shock tubes are used to load circular metal plates by pressure waves, causing high strain rate deformations that lead to inelastic deformations up to rupture. The plates can be loaded repeatedly and alternately from both sides. In order to record displacements and deformed shapes, a short time measurement technique developed in recent years is applied, consisting of capacitive displacement sensors and piezoelectric pressure sensors suitable to record signals during the impulse period in the range of several microseconds.Parallely, numerical simulations are carried out, using different viscoplastic constitutive equations and damage laws. In order to determine the elastic, hardening and viscous parameters of the considered materials, tension tests at different strain rates are carried out seperately. The damage parameters are identified by the change of elastic stiffness in cyclic tension tests.

Advanced instrumentation for dynamic material testing. **Stefan Hiermaier** (Ernst-Mach-Institute, Germany), Frank Huberth (Ernst-Mach-Institute, Germany), Thomas Meenken (Ernst-Mach-Institute, Germany) GA/MT3552/004

Predictive capability of numerical methods in computational mechanics means the ability to predict structural response under varying loading conditions, change of geometries and variations in boundary conditions without adaptation of material parameters. Only with that capability approved, numerical simulation can be treated as a useful tool in engineering design.
In order to meet the mentioned demanding to a predictive tool, the mathematical model describing the material behaviour has to cover all relevant characteristics in the physical behaviour of the modelled material. Additionally, the free parameters in the model need to be derived from precise material tests under well defined stress and strain states. The latter, a precisely known combination of stresses and strains in the sample, is what distinguishes a material test from a component or validation test.
Therefore, it is of primary importance for material characterization to guarantee the assumed stress and strain states in a test set-up or to take changes into consideration if necessary. A more complex the material behaviour and the more dynamic the loading situation, the harder it gets to guarantee these demands. That is why material tests under high strain rate conditions need additional attention. Wave propagation effects cause transient stress-strain states.
Two specific topics will be covered in this paper. One concerns the non-constant volume under plastic deformation of some polymers. Test set-ups and enhanced qualities of multi-directional optical strain measurement with regard to volume change will be proposed along with the related additional modelling efforts. Secondly, the special case of testing low impedance materials under high strain rates in the range of $10^2\ 1/s$ to $10^3\ 1/s$ will be introduced as an example to identify the admissible phases in the testing.

Identification of the shoulder joint centre. **Tony Monnet** (Université de Poitiers, France), Claude Vallée (Université de Poitiers, France), Kossi Atchonouglo (Université de Poitiers, France) GA/MT3870/004

The analysis of joint forces and moments underlying human movement has typically been based on inverse dynamics. Poor estimations of the joint centre locations have led to the distortion of computed angles and moments. Joints centres can be estimated using a predictive or a functional approach. The main sources of error of the predictive approach are: marker location, regression uncertainty and anthropometric measurement. The functional approach is affected by the presence of noise. In this paper we propose a functional method requires only position of markers in proximal and distal segments. The joint centre is then localized as the point belonging both segments by solving a linear system. The method is applied for two different movements. Results are the same for the two movements and are very reproductible.

Out-of-plane displacement measurement near the crack tip during a crack propagation: validation of a 3D formulation for a specimen in PMMA loaded in mode I. **Fabrice Bremand** (Université de Poitiers, France), Stephen Hedan (Université de Poitiers, France), Valery Valle (Université de Poitiers, France), Mario Cottron (Université de Poitiers, France) GA/MT3872/004

This paper proposes to validate experimentally a 3D formulation of the out-of-plane displacement at the vicinity of the crack tip during crack propagation for specimens loaded in mode I. For that the experimental data of the out-of-plane displacement near the crack tip is made using a Michelson interferometer. This technique allows determining the relief variations of a few microns. With the obtained interferograms, we can extract the phase (thus the relief) by using a new numerical approach based on the principle of images correlation between real fringes and virtual fringes. Two tests were realized in the PMMA specimens loaded in mode I with the same loading and the same crack propagation velocity. We compare the experimental results with the 2D theory of Westergaard in plane stress hypothesis and a proposed 3D formulation. This one was given for specimens loaded in mode I and for static cracks. It is function only of 3D effects related to Poisson's effect. However in dynamic, the transient effects appear and are related to the crack propagation velocity. The 3D effects and transient effects lead to results equivalent to experimental ones in terms of displacement but are completely different to results given by the 2D theory near the crack tip. From experimental results, an optimisation process is performed to get the three constants defining the 3D formulation as well in static as in dynamics. We note that these three parameters are equal for two tests. We can show that these three constants are independent of the crack length, and of the dynamic stress intensity factor. In conclusion, a Michelson interferometer associated to a numerical analysing technique for a single image is powerful tool for the relief study near the crack tip during crack propagation. The 3D formulation, we proposed in static, can be extended in dynamic studies by taking into consideration the 3D and transient effects during crack propagation.

On buckling of carbon nano-tubes. **Grzegorz Litak** (Technical University of Lublin, Poland), Alois Steindl (TU Wien, Austria), Hans Troger (TU Wien, Austria) GA/CT1266/004

We investigate a single walled Carbon Nanotube under an axially-directed compressive line loading applied at both of its edges. The expected buckling behavior we study by application of a molecular computation approach ([1]). We formulate a global potential and search for its minimum to obtain the equilibrium configuration. Using besides the main parameter, which is the value of the loading, as second parameter the diameter of the tube, we are able to define the critical value of the diameter, for which we obtain the coincident case of Euler and local shell buckling.

The stability of a pre-stressed annular thin film in tension. **Ciprian Coman** (University of Glasgow, UK) GA/CT2749/004

Asymptotic properties of the neutral stability curves for a linear boundary eigenvalue problem which models the wrinkling instabilities of an annular thin film in tension are considered. The film is subjected to imposed radial displacement fields on its inner and outer boundaries and, when these forces are sufficiently large, the film is susceptible to a wrinkling instability. The critical values at which this onset occurs are dictated by the solution of a fourth-order ordinary differential eigensystem whose eigenvalue λ is a function of $\mu\,(\gg 1)$, a quantity inversely proportional to the bending stiffness of the plate, and n, the number of wrinkles that occur around the film. Previous numerical studies have provided information as to the form of $\lambda(\mu, n)$ but, by their very nature, these are unable to address certain important questions concerning the preferred instability mode or the size of imposed displacement field necessary to induce wrinkling in the thin-film limit. Here WKB and boundary-layer asymptotic methods are used to examine these issues and comparisons with direct numerical simulations made.

this is joint work with Andrew P. Bassom (University of Western Australia). The financial support from The Carnegie Trust for the Universities of Scotland, and from the University of Glasgow are gratefully acknowledged.

Numerical analysis of telephone-cord buckling mode delamination of compressed thin films. **Viet Dung Pham** (Institut für Werkstoffe und Mechanik im Bauwesen„ Germany), Friedrich Gruttmann (TU Darmstadt, Germany) GA/CT2970/004

Experiments of equi-biaxial compressed thin films on substrates provide different forms of delaminations. In Reference [1] the authors perform measurements on compressed diamond-like carbon films (DLC) on nominally flat glass substrates to characterize the various forms of blisters. Straight-sided buckles are rarely observed. In contrast to that the so-called telephone cord delamination occurs in many systems with applied high residual stress levels.

In the presentation we consider the equi-biaxial compressed thin films on rigid substrates. Since small geometrical imperfections are used to initiate buckling. A 5-parameter Reissner-Mindlin shell model for thin films is used, where the interface between film and substrate is chosen as the reference surface. The used 8-noded interface element is compatible with the 4-noded shell element. For the interface we postulate the existence of a cohesive free energy as a function of the opening displacement vector and internal variables. For the irreversible delamination process we use a cohesive law either of a exponential type with constant given parameters or of a bi-linear type, where parameters depend on the combination of modes I, II and III. In order to model the large delamination exactly we use the energy criterion of the steady-state growth.

Comparative analysis of description of elastic plane waves by Murnaghan and Signorini nonlinear models. **Jeremiah Rushchitsky** (Timoshenko Institute, Kyiv, Ukraine), Carlo Cattani (Università degli Studi di Salerno, Italy) GA/CT2225/012

An attempt is realized to outline in the chronological ordering the development of theory of elastic nonlinear waves in materials, where five stages are emphasized. Further the attention is concentrated on distinctions and similarities in the analytical description of propagation of plane polarized hyperelastic waves within the assumption that nonlinear deformation of material takes place by the Murnaghan and Signorini models, as well as in matching the fundamentals of propagation the mentioned waves when waves are described by theories based on distinct enough Murnaghan and Signorini potentials. For the family of fibrous composite materials with micro- or nanofibres, a computer simulation of evolution of initial harmonic profiles is studied. A few short movies on distinct scenarios of evolution will be presented.

A contribution to the modelling of metal foams on the mesoscale. **Daniel Schwarzer** (Universität Karlsruhe, Germany), Sébastien Gatouillat (Universität Karlsruhe, Germany), Carsten Proppe (Universität Karlsruhe, Germany) GA/CT1890/004

Due to their useful properties in lightweight construction and due to their excellent behaviour in energy absorption for example in crash mechanics, metal foams became an interesting and in literatur often examined material. In this talk, the focus of the investigations lies on the mechanical properties of mainly metal foams and their modelling on the mesoscale. Starting with the examinations of analytical models based on Gibson and Ashby [1], different extensions of these models are taken into account and their influence on the mechanical properties are dicussed and compared. The goal of this contribution is to find a model, which shows the important effects of the foam on the mesoscale, but stays simple enough to be useful in further investigations in multiscale modelling of foams.

Damping of structural vibrations using an electromotive eddy current damper. **Siewert Christian** (Universität Hannover, Germany), Lars Panning (Leibniz Universität Hannover, Germany), Christoph Gerber (ALSTOM, Schweiz, Switzerland), Andreas Hohl (Universität Hannover, Germany), Buerge Annika (Universität Hannover, Germany) GA/CT2404/004

Structural vibrations are normally the cause for high cycle fatigue failure (HCF) in technical structures. For example, the blades of rotating bladed turbine disks are subjected to fluctuating gas forces during operation that cause blade vibrations. One of the main tasks in the design of turbomachinery blading is the reduction of the vibration amplitudes of the blades to avoid high resonance stresses that can cause a HCF blade damage. It is well known that the vibration amplitudes of the blades can be reduced significantly to a reasonable amount by means of friction damping devices such as underplatform dampers, tip shrouds and damping wires.

If the temperature of the working fluid is not excessively high, the use of an electromotive eddy current damper can be a possible alternative to this well known classical friction damping devices. If a conducting material is moving in a stationary magnetic field, eddy currents are generated inside the conductor. These eddy currents cause an energy dissipation effect, therefore a damping effect is generated. This damping effect can be used to reduce the resonance amplitudes and therefore to decrease the risk of a HCF failure. In contrast to classical friction damping devices, the eigenfrequencies of the structure are not affected by the use of an electromotive eddy current damper.

In this paper, the electromotive eddy current damper model presented in [1] is extended. The modified model is validated by comparing measured and simulated data for a beam model. It is shown that the measurements and the simulation results are in good agreement. Furthermore, the electromotive eddy current damper is applied to a turbine blading with shroud and snubber coupling. The results are compared to the results computed with classical friction damping devices with respect to the influence on the vibration amplitude and resonance frequency of a steam turbine blading.

Stability analysis of large flexible, earth-orbiting structures. **Wolfgang Steiner** (FH Oberösterreich, Austria) GA/CT1120/004

Large flexible structures could be one of the most challenging space technologies of the future. A well known example is the *space elevator* enabling astronauts to climb up a 36000km long tether leading to a geostationary orbit. In general we could consider an arbitrary flexible structure in a stationary circular motion around the earth or another celestial body.

Usually such systems require two problems to be solved: the strength of the materials and an overall stability analysis. The latter one is a non-trivial task since in orbiting systems not the angular rate but the angular momentum must be kept constant when applying for example Dirichlet's criterion. In particular, this fact becomes important, if the system's dimension is in the magnitude of the orbital radius. Therefore, this presentation will focus on a general applicable method to discuss the stability of flexible earth orbiting structures.

The analysis process bases on the *reduced energy momentum method* by J.C. Simo, T.A. Posbergh and J.E. Marsden, which has been specialized to systems with cyclic coordinates by the author. In the presented approach the second variation of an *amended potential* is derived from the system's equilibrium configuration, which is obtained from a standard Finite Element Analysis with common solvers such as ABAQUS. A practical example will be discussed to demonstrate an application of the method.

Basic studies on the dynamics of rotating circular structures. **Maik Brinkmeier** (Universität Hannover, Germany), Udo Nackenhorst (Leibniz Universität Hannover, Germany) GA/CT2147/004

In this presentation the dynamic effects due to rotation on spinning circular structures will be discussed by analytical, experimental and numerical investigations. Basic phenomena of spinning are studied on the analytical solution of a spinning ring. The observed effects will be underlined by rather simple experimental investigations on a rotating wine glass. Based on this fundamental knowledge special attention has to be payed to the finite element modeling and implementation of

the eigenvalue analysis of gyroscopic systems, which requires the numerical solution in complex numbers. Besides the influence of rotational speed, the disturbances due to rolling contact will be discussed on rotating tubes as well as detailed finite element models of rolling tires. The application of these techniques with emphasis to the prediction of tire noise will be outlined.

Nonlinear dynamics of an inclined cable subjected to boundary motion conditions. **Anna Woszczyna** (Wroclaw University of Technology, Poland), Danuta Bryja (Wroclaw University of Technology, Poland), Dawid Prokopowicz (Wroclaw University of Technology, Poland) GA/CT2210/004

The paper is devoted to the dynamic modelling of an inclined cable being an element of suspended structures such as cable-stayed bridges, suspension bridges, suspended pipelines [1,2]. Spatial cable vibrations are considered from the viewpoint of kinematic excitation caused by a motion of connecting points between the cable and suspended structure or pylon. Basing on equilibrium state analysis of a differental cable element in deformed configuration, the nonlinear equations describing in-plane and out-of-plane cable vibrations are derived. The final general form of the equations is obtained by applying the standard Galerkin's procedure. General equations are adjusted to the particular types of cable geometry distinguished by a small or large sag-to-span ratio and horizontal, vertical or inclined cable chord. The proposed cable model is formulated so as to be useful for analyzing suspended structures by substructure approach [3]. Examples of numerical studies: vibrations of planarly suspended beam and spatially suspended pipeline are presented for invesitigating the nonlinear behaviour of structures.

Non-linear vibrations of a ropeway system with moving passenger cabins. **Marta Knawa** (Wroclaw University of Technology, Poland), Danuta Bryja (Wroclaw University of Technology, Poland) GA/CT2235/004

The dynamic model of a carrying rope for a bicable aerial ropeway is formulated. The cable is anchored at one end point of the multi-span track and tensed by the counterweight at the other end point. Dynamic behavior of the carrying rope is considered independently from the hauling rope [1]. To describe non-linear in-plane vibrations excited by moving masses of passenger cabins a closed form model with a Green-Lagrange relative strain is adopted. The equations of motion of the system are derived on the basis of Lagrangian's equations with a Ritz approximation of cable displacement is applied [2]. Numerical simulations of the dynamic response of the system are presented for investigating the non-linear behavior of the cable.

Radiation problem of normal stress-loading of bore surface. **Arnold Snitser** (Vernadskiy Tavrichesky National University, Ukraine) GA/CT4309/012

We study the radiation of elastic waves which are generated by normal loading of a circular strip applied on the free surface of a cylindrical cavity in elastic medium and having a harmonic time-dependence. The stress and displacement field is represented by contour integrals. By using the saddle-point method stress and displacement asymptotic expansions in the far field were obtained. It is shown that in the far field P-waves bring radial displacements and stresses, and perpendicular to these, displacements and stresses are caused by SV-waves.

As a result the relative distribution of wave-energy radiation in accord to type of waves (P-, S- and Biot surface waves) and its dependence on vibrator's frequency, relative diameter of the hole and width of circular strip loading were obtained. In the paper orientation diagrams of radiation of elastic P- and S-waves and their dependencies on frequency and geometrical parameters are presented too.

Stochastic FEM with local polynomial-chaos approximations. **Carsten Proppe** (Universität Karlsruhe, Germany) GA/CT2125/004

Polynomial-chaos expansions of response quantities have been widely used in Computational Stochastic Mechanics and are well documented. Introduced in conjunction with a truncated Karhunen-Loève-representation of the input random field, they represent global approximations in the Hilbert space of functions of (usually standard Gaussian) random variables. However, the global approximation character may lead to inefficient convergence behavior for higher order response moments or small response probabilities. This has been pointed out recently in [1]. Therefore, after the multiplicative decomposition in deterministic and a random part, local polynomial expansions of the solution are introduced by partitioning the domain of random variables and the physical domain. By carefully choosing the local basis [2], the problem decouples in the random domain. The expansion coefficients can then be determined independently by parallel processing. Moreover, local expansions allow to construct new hybrid simulation schemes, that is, combinations of analytical and simulation based techniques. For reliability estimation, the expansion can be interpreted as a local response surface. Starting from the global approximation, a local response surface can be constructed by computing the design point and sensitivities. After that, suitable local approximations can be introduced by decomposing the region of most probable failure. [1] R. V. Field Jr., M. complex loading and loss of the stability of the cylindrical shell: experimental investigation. **Vladimir Fedenko** (Dnipropetrovs'k National University, Ukraine) GA/CT1690/004

The numerous experimental investigations, devoted to the behaviour of ma-terials at complex loading, showed that for the same stresses, but reached by the various paths, the strain states are various. This fact gives the foundation to assume that for complex loading paths effect of "loading history" on values of stability pa-rameters of thin-walled constructional element, working outside elasticity, is pos-sible.

Investigation of loss of stability and bearing capacity of smooth cylindrical shells made from an aluminum alloy was carried out by experimental methods. The shell slenderness ratio (the ration of shell radius to its thickness) was equal 23.6 and 26.2 and shell was loaded by axial compression and external hydrostatic pres-sure. The results were obtained for simple and complex loadings. The simple load-ing which was carried out in experiments, is represented in loading space by a ray with various slope, and the complex loading is realized in the same plane by two-segment lines in which the first loading segment is carried out by axial compres-sion, and second segment - by combined action of axial compression force and ex-ternal hydrostatic pressure. The angle of the break of loading path was chosen in the interval $[0,\pi/2]$, and the length of the first segment was chosen equal to $0.95P^*$, where P^* Ű critical parameter of compression force at simple load-ing.

Areas in which depending on shell slenderness ratio the complicated loading raises critical values of exterior loadings from 14% up to 23% are founded. It is experimentally shown, that the phenomenon of raise of bearing capacity of a shell is expression of deformation anisotropy which is "induced" in a material of a shell as a result of prior complex loading.

The influence of semi-rigid connections on the shakedown of elasto-plastic frames. **Sandor Kaliszky** (Budapest University of Technology and Economics, Hungary) GA/CT1078/004

The main structural elements of steel framed multi-storey structures are the columns, the beams and their connections. The assumption that the connections are either rigid or pinned has been widely applied in the past. The actual behavior of the connections is however somewhere between these limits and they are semi-rigid [1,2]. This circumstance can influence significantly the behavior of the structure therefore has to be taken into account in the analysis and design. The aim of this paper is to analyze the influence of the semi-rigid connections on the shakedown of elasto-plastic steel framed structures under multi-parameter static loading. In addition to the shakedown analysis, to control the plastic behavior of the structure, bound on the complementary strain energy of the residual forces is also applied [3]. The formulation of the problem yields to nonlinear mathematical programming which is solved by the use of sequential quadratic algorithm.

The results of the numerical calculation are in agreement with the expectation, that the stiffness of the semi-rigid connections can influence significantly the magnitude of the shakedown parameter. In the presented example the average change of this parameter 15–20%. However, this effect depends very much on the number of the semi-rigid connections, the arrangement of the structure and the loads, the ratio of the lengths of the beams and columns and several other circumstances. Therefore further investigations are necessary to make more general statements.

A new approach to analysis of free beam vibrations. **Vasily Saurin** (Institute for Problems in Mechanics RAS, Russian Federation), Georgy Kostin (Institute for Problems in Mechanics RAS, Russian Federation) GA/CT808/004

Based on the linear theory of elasticity and the method of integrodifferential relations a countable system of ordinary differential equations is derived to describe 3D longitudinal, lateral, and torsional free vibrations of rectilinear beams. In the approach under consideration the stress-strain relation is specified by an integral equality instead of the local Hooke's law. After expansion of unknown stress and displacement functions in polynomial series with respect to transversal Cartesian coordinates and system decomposition due to domain symmetry the consistent boundary value problems are solved and the bilateral estimation criteria of solution errors are proposed in order to analyze the algorithm convergence rate. The influence of geometrical and elastic characteristics of rectilinear beams on eigenfrequencies and shapes is investigated. The various kinds of longitudinal, lateral, and torsional free motions are found out in the models under study.

The vibrational behaviour of bladed disks with multiple coupling devices. **Andreas Hohl** (Universität Hannover, Germany), Buerge Annika (Universität Hannover, Germany), Siewert Christian (Universität Hannover, Germany), Lars Panning (Leibniz Universität Hannover, Germany) GA/CT2480/004

In turbomachinery applications turbine blades are subjected to high static and dynamic loads. Static loads are due to centrifugal stresses and thermal strains. Especially the dynamic excitation caused by fluctuating gas forces results in high vibration amplitudes which can lead to high cycle fatigue failures (HCF). Therefore, in practical applications, coupling devices like underplatform dampers, lacing wires und tip shrouds are installed to the structure. In case of blade vibrations the relative displacements between these coupling devices and the blades generate friction forces. The resulting energy dissipation provides additional damping to the structure. Furthermore, coupling devices, in particular tip shrouds, snubbers and lacing wires, increase the stiffness of the structure. Hence, they lead to a shift of the resonance frequencies.

So far, only effects of single coupling devices and the influencing properties have been examined. Within this paper the effect of multiple couplings is determined and compared with single couplings. The forced response of multiple coupled turbine bladings is calculated under consideration of geometrical and mechanical parameters of the blading and contacts, respectively. The results are compared with the single coupled blading. Furhermore, different coupling devices like underplatform dampers, connecting pins and shrouds are compared with respect to their effectiveness. Especially the influence on the resonance frequency and the vibration amplitudes is analysed.

The results of the simulation is verified in measurements at a two-blade non-rotating test rig with an underplatform damper and connecting pins in different configurations.

Elastic–plastic states of a rotating inhomogeneously-heated strain-hardening hollow shaft. **Eray Arslan** (Middle East Technical University, Turkey), Ahmet Nedim Eraslan (Middle East Technical University, Turkey), Werner Mack (TU Wien, Austria) GA/CT1952/004

Structures like rotating heat pipes are loaded by mass forces as well as by radial temperature gradients. To optimally utilize the material, it is of interest not only to predict the onset of yield but also, since plastic deformation may be admitted under certain circumstances, to study the behaviour in the elastic-plastic range. While several investigations on either mechanically or thermally loaded hollow cylinders are available, a solution for combined loading by rotation and an inhomogeneous temperature distribution has not been given hitherto; due to the non-linearity inherent in elastoplasticity, it cannot be found by mere superposition. Hence, based on Tresca's yield condition and the flow rule associated with it, the distribution of stress, strain and displacement in a linearly strain hardening elastic-plastic hollow shaft subject to monotonously increasing angular speed and a positive radial temperature gradient is investigated. Presupposing circular symmetry and plane strain conditions, the problem is amenable to an analytical treatment. A main result is that depending on the temperature difference between the outer and inner surface qualitatively different types of solutions may occur, and that a moderate temperature difference on the one hand reduces the elastic limit angular speed but on the other hand increases the fully plastic angular speed as compared to the isothermal case.

Numerical benchmarks for creep-damage modeling. **Holm Altenbach** (Universität Halle-Wittenberg, Germany), Yevgen Gorash (Kharkiv National University of Technology, Ukraine), Konstantin Naumenko (Universität Halle-Wittenberg, Germany) GA/CT2548/004

The aim of creep modeling is to reflect basis features of creep in structures including the development of inelastic deformations, relaxation and redistribution of stresses as well as the local reduction of material strength. A model should be able to account material deterioration processes in order to predict long term structural behavior and to analyze critical zones of creep failure. In recent years general purpose finite element codes have become the widely accepted tool for the structural analysis. To consider the creep and damage processes, a specific constitutive model with selected internal state variables, special types of stress and temperature functions as well as material constants identified from available experimental data should be incorporated into the commercial finite code by writing a user defined material subroutine. To assess the reliability of the developed subroutine as well as the accuracy of the results with respect to the mesh density, the time step, and iteration methods, numerical benchmark problems are required.

In this lecture we present several problems of creep-damage mechanics which can be solved by approximate analytical methods. The reference solutions will be compared with the finite element solutions by ANSYS and ABAQUS finite element codes with developed user subroutines.

Nonlinear deformation of cylindrical shells with variable parameters. **Olga Tumashova** (Lvivska Politechnica, Ukraine) GA/CT3285/004

The present paper is devoted to working out the effective approach to numerical research in geometrically nonlinear statement of stress-strained state of flexible shallow cylindrical panels of finite dimensions with variable hardness or variable curvature along the generatrix y and solving two-dimension nonlinear problem based on consecutive application of the methods of Vlasov-Kantorovich, methods of linearization and discrete orthogonalization. Consided the deformation of the elastic shallow cylindrical panel with variable thickness and curvature is under the influence of normal surface load q.

Elastic-plastic sandwich beams with optimized properties for the impact case. **Jürgen Schmidt** (Universität Erlangen-Nürnberg, Germany), Werner Winter (Universität Erlangen-Nürnberg, Germany), Günther Kuhn (Universität Erlangen-Nürnberg, Germany) GA/CT2898/004

The objective is to obtain plane lightweight structures having an optimal performance concerning impact loadings. For this purpose sandwich structures with solid faces and cellular cores exhibit suitable multifunctional characteristics which enclose high structural rigidity and distinct energy absorption. To determine optimal design the used criteria cover failure mechanisms that dissipate maximum energy and lead to minimum displacement in addition with minimum structural thickness and weight.

In this contribution sandwich beams consisting of stainless steel faces and aluminium foam cores are subjected to low velocity impact. The identified design variables are the top and bottom face thicknesses as well as the core thickness. The design approach for this test configuration is based on simulation results performed by an explicit finite element code. Experimental tests are carried out on cellular aluminium to fit the used material constitutive law. Limits of accuracy are revealed for this material model in which material inhomogeneities in the cellular metal are the main reason for scatter in test results. For the applied optimization method it is gone into details.

Optimization results are presented and discussed. Beyond that results are compared in experiment and simulation to assess the correlation.

Application of the conditional moments method to multi-layered anisotropic shells. **Wolfgang Müller** (TU Berlin, Germany), Ralf Wille (TU Berlin, Germany), Lidiia Nazarenko (TU Berlin, Germany) GA/CT2345/004

In the present paper the model of non-linear deformation of stochastic composites under elevated loading is applied for investigation of the stress-strain state of tires. The tire is described geometrically non-linear as a multi-layered anisotropic torus shell with low transfer shear stiffness. The layers are treated as rubber matrix strengthened by metal or cord fibres. The problem can be solved stepwise. At the first stage we determine the effective properties of each of the layers and of the whole tire by the method of conditional moment functions. This method is based on the solution of statistically non-linear equations of the mechanics of a deformable solid. Based on the analytical and numerical approach the algorithm for the determination of non-linear deformative properties of such a material is constructed. Then the stress-strain state of the tire is studied on the basis of equations of shell theory. In this case the tire is considered as a homogeneous shell with averaged properties. At the next stage local problems of tire mechanics can be solved by using the finite element method considering the real structure of the tire in the place of stresses concentration. Boundary conditions for the local problem can be formulated on the basis of the solution of the global one.

Investigation of orthotropic non-thin non-circular varying thickness cylindrical shells using B-splines. **Sergiy Yaremchenko** (National Academy of Sciences of Ukraine, Kyiv) GA/CT1864/004

Non-circular cylindrical shells made of inhomogeneous anisotropic materials are widely used for building of structure elements in modern engineering. The effective approach is presented to this class shells design. Elliptical and corrugated cross-section cylindrical shells of varying thickness with hard clamped butt-ends is under consideration. A material of shell is orthotropic. The Timoshenko theory is used for description stress-strained state of shells. It lets us to take into account shear deformation and to solve problems for non-thin shells.

Let s be coordinate in directrix and θ be angular parameter in generatrix direction. The decision functions are components of displacement vector u, v, w and complete turn angles ψ_s, ψ_θ. Resolving system consist of five equations with partial derivatives and may be represented as

$$\mathcal{L}\bar{N} + \bar{f} = 0$$

where $\bar{N} = \{u, v, w, \psi_s, \psi_\theta\}$, $\mathcal{L}$ is linear differential operator of second order, and $\bar{f}$ are functions that represent the loads. Adding boundary conditions to the system we obtain two-dimensional boundary problem. Sought quantities are represented as

$$u = \sum_{i=0}^{N} u_i(\theta)\varphi_i(s), v = \sum_{i=0}^{N} v_i(\theta)\varphi_i(s), w = \sum_{i=0}^{N} w_i(\theta)\varphi_i(s),$$
$$psi_s = \sum_{i=0}^{N} \psi_{si}(\theta)\varphi_i(s), \psi_\theta = \sum_{i=0}^{N} \psi_{\theta i}(\theta)\varphi_i(s), \quad (1)$$

where u_i, v_i, w_i, ψ_{si}, $\psi_{\theta i}$ are unknown functions and φ_i are linear B-splines combinations of third power, that satisfy boundary equations on the butt-ends. If we put these latter expressions into the main equation, and into boundary conditions on straight contours, and demand satisfaction at $N+1$ points of collocation, we obtain a one-dimensional boundary problem with system of ordinary differential equation of $10(N+1)$ order, which is solved by the stable numerical method of discrete ortogonalization.

Model adaptivity and Green's functions. **Friedel Hartmann** (Universität Kassel, Germany) GA/CT3077/004

The reliability of computer predictions has become known as the subject of Verification and Validation (V&V). The verification process addresses the quality of the numerical results while the validation process addresses the quality of the model. Both problems center on the approximation of the Green's function of the governing equation. How accurate is the approximation of the Green's function and does the model approximate the correct Green's function? The numerical error as well as the modeling error strongly depend on the nature of the Green's functions, their rate of decay, their domain of influence and their shifts (Green's function are pseudo differential operators).

Things become additionally complicated in that structures are made of composite materials so that homogenization techniques tend to blur the picture and multi scale modelling complicates the resolution of the (numerical) Green's functions. We know that the error in a (linear) FE analysis is attributable to the error $G_0 - G_h$ in the Green's functions and to gain accuracy we must improve the projections G_h. Adaptive methods based an this duality technique have been applied very successfully in recent years. This technique is also the key to the assessment of the modelling error. Unlike standard error analysis where we study the numerical error $u - u_h$, we now focus also on the modelling error $u - u_0 + u_0 - u_0^h$ where u_0 is the exact solution of a simplified problem (after some homogenization techniques are applied) and u_0^h is its FE approximation. The issue are therefore techniques which allow to adaptively refine a model so that the sensitivity and reliability of the model can be 'guaranteed' with regard to a certain output value. The *a posteriori* error estimates required can be developed in the same framework as the now 'classical' duality approach of Rannacher [1]. We shall outline a general technique for comparing coarse and fine models and to produce error estimates for computing modelling errors.

Energy-momentum conserving integration with AES elements. **Melanie Müller** (Universität Siegen, Germany), Peter Betsch (Universität Siegen, Germany) GA/CT2650/004

Assumed enhanced strain (AES) elements (see, for example, [1]) are well-know to exhibit improved convergence behavior, especially in the context of bending dominated situations and in the incompressible limit. In the present work we focus on the application of AES elements to nonlinear elastodynamics. In particular, we aim at the design of energy-momentum schemes for the stable numerical integration of the semi-discrete equations of motion. For this purpose we make use of the notion of a G-equivariant discrete derivative introduced by Gonzalez [2] in the framework of general finite-dimensional Hamiltonian systems with symmetry.

Energy-momentum schemes for large deformation contact and domain decomposition. **Christian Hesch** (Universität Siegen, Germany), Peter Betsch (Universität Siegen, Germany) GA/CT2649/004

In the present talk large deformation contact problems as well as domain decomposition problems of flexible bodies are addressed within a nonlinear finite element framework.

Actual developments like the mortar method yield a variationally consistent description of the contact surface, see for example, Puso and Laursen [1] and Wohlmuth [2]. This approach passes the patch test and is characterized by a robust behavior.

Over the past years the development of energy and momentum consistent 'mechanical' integrators for the differential algebraic equations (DAEs) have achieved major improvements. Energy consistent mechanical integrators have been recently developed for DAE-formulations of constrained mechanical systems (Gonzalez [3], Betsch and Steinmann [4]).

We aim at the application of the mechanical integrators to the mortar method used for both, contact problems and domain decomposition problems. Special requirements for the algo-

rithmic conservation of energy in the case of high velocity impact are analyzed.

Two mixed finite-element formulations with area-bubble functions for tetrahedral elements. **Ismail Caylak** (Universität Paderborn, Germany), Rolf Mahnken (Universität Paderborn, Germany) GA/CT1162/004

We address the solution of geometrically linear elastic problems for three dimensional solid mechanics using tetrahedral finite elements. Starting from a five field weak formulation involving fields for conformal displacements, nonconformal displacements, pressure, enhanced strains and stresses, both, the method of incompatible modes and the enhanced strain method are considered as special cases. As a key idea, area bubble functions are used for both mixed finite element formulations in order to enrich the displacement field and the enhanced strain field, respectively. Appropriate conditions for convergence (satisfaction of the patch test) and stability (unique solution of FE-matrix equation) are verified.

In the representative examples firstly a numerical verification of the patch test is obtained. Two additional examples, Cook's membrane problem and a plate with a ring hole, illustrate the good performance of the presented approach in comparison to existing finite element formulations.

Displacement field analysis of the topology optimized structure. **Ryszard Kutylowski** (Wroclaw University of Technology, Poland) GA/CT2990/004

In this paper for the topology optimization process the minimum compliance approach is used with FEM as very useful method for numerical realization of the problem. During the optimization process homogenized domain changes into discrete structure which means the final structure consists of the many optimal placed bars. The analysis of the deformed structure and the deformed elements is done from the displacement field point of view. It can be noticed some of the elements reduce their size, some of them increase their size. It depends on the element status (void-empty, stressed or not stressed).

The question arises: is the topology optimization process cause of the negative Poisson ratio for some parts of the structure?

A locking-free element formulation for 3D nonlinear FE problems. **Markus Kraus** (Universität Erlangen–Nürnberg, Germany), Johannes Geisler (Universität Erlangen–Nürnberg, Germany), Kai Willner (Universität Erlangen–Nürnberg, Germany) GA/CT2559/004

In today's simulations, mechanical systems with large deformations or other nonlinear phenomena are often considered. To solve those problems with the finite element method, isoparametric element formulations with linear shape functions are preferred, due to robustness and computational efficiency. A major disadvantage of these elements is the appearance of locking effects in bending problems and in the limit of incompressibility. These effects occur because of a mere numerical insufficiency of the shape functions that leads to an artifical stiffening of the whole system.

All methods to avoid locking are based on two different techniques. Beside reduced integration with additional stabilization, many formulations are based on mixed variational principles, like the enhanced assumed strain (EAS) method.

In this work a locking free brick element formulation using reduced integration and hourglass stabilization is discussed. In general, the necessary stabilization parameters can be chosen arbitrarily, but here they are derived from an enhanced assumed strain formulation and thus have a real physical character. The element performance is demonstrated in different large deformation problem examples.

Automatic adaptation of the integration formula in thickness direction for solid-shell elements. **Georgios Michaloudis** (Universität Karlsruhe, Germany), Karl Schweizerhof (Universität Karlsruhe, Germany) GA/CT2501/004

In problems with high stretching and intense thickness reduction general three-dimensional material laws as well as strains and stresses in thickness direction are required, imposing the use of *Solid-Shell* formulations. The Solid-Shell elements possess the ability to illustrate directly deformations and stresses in thickness direction, providing the appropriate 3D-continuum discretization, see [1] and [2].

In problems such as metal forming with large deformations where plastic stresses in thickness direction are developed, appears the necessity of a more accurate integration through thickness using more integration points; e.g., Gauss points, increasing respectively the computational time and effort. In this contribution a new algorithm is proposed for the automatic adaptation during the computation of the integration formula in thickness direction. Thus, the computation starts with the minimum required number of integration points in thickness (e.g., two) and during the computation the integration points are increased only in the regions where is needed; e.g., if plastic stresses occur.

Error analysis as well as simple engineering criteria define the time-point and the regions to increase the number of integration points. Application of different integration formulae (e.g., Gauss–Lobatto) in a subdomain integration approach is also presented, see [3] and [4]. The method provides an efficient compromise between accuracy and computational time, as high order integration formulae are applied in an adaptive fashion but only to the elements where and at those time-points when it is needed.

A novel polygonal finite-element method. **Alexandru Constantiniu** (TU Kaiserslautern, Germany), Paul Steinmann (TU Kaiserslautern, Germany) GA/CT2475/004

In recent years we saw an emerging interest towards using arbitrary polygonal elements in discretization schemes. Latest advances in the construction of interpolants have allowed the use of new building blocks for tessellations, other than n-simplices and regular n-gons.
A novel polygonal finite element method is proposed, based on a hybrid nodal-element approach. Two popular concepts are used, namely Voronoi diagrams and generalized barycentric coordinates. Starting from a classical Delaunay tessellation, we transform it into an adaptive one by subsequently applying a Delaunay circumcenter rule. Polygons are formed by merging simplices intersected by line segments between their barycenters and circumcenters. Constructed in a straightforward and iterative manner, such a tessellation is unique and bounded in computational time. A simple to evaluate form of rational barycentric coordinates for higher dimensions is applied. They have desired properties and reduce to conventional barycentric coordinates in the case of simplices. Over the representative domains around the nodes a stabilized nodal integration scheme is used.
The method has been compared with the classical Delaunay tessellation scheme when applied to scattered data interpolation. A similar interpolation error was obtained, however using approximately 30% fewer elements, with improved geometric properties. Simplices have no angles greater than 90^o, meaning small and large angles are avoided and polygons have as rounded shapes as possible.
Without any predefined connectivity between the nodes, the method can be seen as an extension of the Finite Element Method with which it overlaps for simplices and regular nodal distributions.

Two-grid and hanging-node-based mesh refinement with application to metal forming simulations. **Xin Gu** (Universität Dortmund, Germany), Christian Hortig (Universität Dortmund, Germany), Bob Svendsen (Universität Dortmund, Germany) GA/CT2459/004

In the current work, a two-grid-based h-adaptivity method is combined with a hanging-node based mesh generation approach for application in particular to metal forming simulations. In the h-adaptivity approach, the elements are selected to be refined based on desired mesh density. Hanging node and constraint equation are introduced to handle the transition between different element levels. Alternatively, hanging nodes can be eliminated by using trapezoidal method. In this method, the elements containing hanging node are first split to triangles in an appropriate way, and then the adjacent triangle and quadrilateral which have a common hanging node are merged into a trapezoid. To achieve a prescribed accuracy, a two-grid error estimator controls the h-adaptivity procedure. Example applications of the approach will be discussed.

Aspects of sensitivity analysis using the level-set method in structural optimization. **Monika Rotthaus** (Universität Dortmund, Germany), Franz-Joseph Barthold (Universität Dortmund, Germany) GA/CT1951/004

The level-set method is very common for modelling of structural optimization problems; e.g., multi-material structures. Essentially two different approaches are known. The first method describes the shape by an implicit function. The weak form is expressed as a Heaviside function of this implicit function and the optimization problem is solved by an iterative procedure. This method is applied to topology optimization by e.g., Belytschko et al. [2].

The second approach is based on the combination of the shape derivative and the level-set method for front propagation, which has been devised by Osher and Sethian. Allaire et al. [1] uses the shape derivative for the minimization problem to compute the advection velocity in the Hamilton–Jacobi equation. The Hamilton-Jacobi equation can be solved numerically by an explicit first order upwind scheme on a Cartesian grid.

We propose a new numerical method for shape optimization of multi-material structures. This approach is based on the level-set method combined with the variational sensitivity analysis. The aim of the present contribution is to point out the essential aspects of this combination and to compare it with the two methods mentioned above. Furthermore, the sensitivity of multi-material structures in terms of various design parameters will be discussed.

Design of cold-formed thin-walled beams with the application of an expert system. **Renata Kasperska** (University of Zielona Gora, Poland), Marian Ostwald (Poznan University of Technology, Poland), Dariusz Mikołajewski (University of Zielona Gora, Poland) GA/CT1797/004

The expert systems are currently used in various disciplines of civil engineering and structural mechanics due to their ability to use symbolic knowledge representations and reasoning capabilities. This paper outlines the application of a knowledge-based expert system built to assist engineers in the designing process and multicriterial optimization of cold-formed thin-walled beams, which are more and more extensively applied in mechanical and civil engineering. The design and implementation of an expert system described in this paper was primarily motivated by a research work on optimal design of thin-walled structures and cold-formed thin-walled beams with monosymmetrical open cross sections conducted by authors and the expert team of Poznan University of Technology, as well as by a study of literature related to the problems of strength and stability of thin-walled beams. In order to develop the expert system, which the overall architecture is presented in the work, a framework called PC-Shell was used. The applied knowledge base includes descriptions of the geometric cross-section characteristics, material and dynamic features of beams and the different discrete and continuous optimization methods, e.g. genetic algorithms. The bi-criteria optimization problem of thin-walled beams is solved on the ground of the minimum in Pareto sense, where beam mass and deflection of the centre of the beam are two optimization criteria. The best optimal solutions are chosen from the set of compromise solutions with the help of preference functions. The work provided optimal parameters of cross-sections of the beams, satisfying the conditions of general and local stability, strength, stiffness of the beam, limiting loading capacity of the beam, structural, technological and exploitation constraints. Results of numerical analysis are presented in the form of tables and diagrams. Plans related to further research are shown at the end of the paper.

Least-squares mixed finite elements with applications to anisotropic elasticity and viscoplasticity. **Alexander Schwarz** (Universität Duisburg–Essen, Germany), Jörg Schröder (Universität Duisburg-Essen, Germany) GA/CT2178/004

The objective of this work is to discuss a least-squares finite element method with applications to physically nonlinear and anisotropic constitutive equations at small strains. The L_2-norm minimization of the residuals of the given first order system of differential equations leads to a functional, which is a two field formulation in the displacements and the stresses, see e.g. [1]. In order to approximate the stresses, shape functions related to the edges are chosen. These vector-valued functions belong to a Raviart-Thomas space, which guarantees a compliant discretization of the required space $H(div,\Omega)$. A characteristic attribute of functions $\mathbf{v}$ in $H(div,\Omega)$ is given by its definition $H(div,\Omega) := \{\mathbf{v} \in L^2(\Omega) : div\,\mathbf{v} \in L^2(\Omega)\}$. Furthermore, standard Lagrange polynomials, which are associated with the vertices of the triangle, are used for the continuous approximation of the displacements. A main focus of the presentation lies on the extension of plane elasticity to anisotropic or nonlinear material behavior. In this context we discuss amongst others transversal isotropic elasticity and viscoplasticity. Further on, the governing equations for the considered formulations for the least-squares mixed finite elements are derived and some numerical examples are presented.

Closest-point projection in contact mechanics: existence and uniqueness for different type of surfaces. **Alexander Konyukhov** (Universität Karlsruhe, Germany), Karl Schweizerhof (Universität Karlsruhe, Germany) GA/CT2454/004

The most important operation for data transfer between contacting bodies in contact mechanics is the closest point projection procedure, where one seeks the projection of a given contact point from one body $\mathbf{r}$, usually called a slave point, onto another contact body, see [1], [2]. The closest point procedure appears also in many other applications such as fluid-structure interactions, computational plasticity etc. The projection problem e.g. for surfaces is usually formulated as an extremal problem

$$\mathbf{F}(\xi^1,\xi^2) = ||\mathbf{r} - \rho(\xi^1,\xi^2)|| \to \min, \quad \longrightarrow (\mathbf{r}-\rho)\cdot(\mathbf{r}-\rho) \to \min, \tag{1}$$

which is solved then mostly numerically. However, then a fundamental problem arises: Does the solution of (1) exist? And, if it exists, then, is it unique for any arbitrary surface approximation? The straightforward answer is given by the result from the convex analysis: if a function $\mathbf{F}(\xi^1,\xi^2)$ is convex in a domain $(\xi^1,\xi^2) \in D$, then the solution of the problem (1) exists and is unique. The goal of the current contribution is to provide this analysis in the local surface coordinate system, introduced for the covariant description of contact problems in [3], [4]. This allows to create a classification of surfaces from its differential geometry point of view onto which a point can be projected uniquely. Thus, a projection domain Ω in 3D can be created a-priori for any arbitrary surfaces including singularities as edges and sharp points, from which any slave point can be uniquely projected onto the given surface. A full set of projection routines is created in order to cover cases with C^2-, C^1- and finally only C^0--continuous situations appearing in practical approximations of arbitrary surfaces.

A mixed finite-element formulation for piezoelectric shells. **Katrin Schulz** (Universität Karlsruhe (TH), Germany), Sven Klinkel (Universität Karlsruhe (TH), Germany) GA/CT2139/004

A finite element formulation to analyze piezo-electric shell problems is presented. A reference surface of the shell is modelled with a four node element. Each node possesses six mechanical degrees of freedom, three displacements and three rotations, and one electric degree of freedom, which is the difference of the electric potential in thickness direction. The formulation is based on the mixed field variational principle of Hu-Washizu. The independent fields are displacements $\boldsymbol{u}$, electric potential $\boldsymbol{\varphi}$, strains $\boldsymbol{E}$, electric field $\vec{\boldsymbol{E}}$, stresses $\boldsymbol{S}$ and dielectric displacements $\vec{\boldsymbol{D}}$. The mixed formulation allows an interpolation of the strains and the electric field in thickness direction. Accordingly a three-dimensional material law is corporated in the variational formulation. It is remarked that no simplification regarding the constitutive law is assumed. The formulation allows the consideration of arbitrary constitutive relations. The normal zero stress condition and the normal zero dielectric displacement condition are enforced by the independent stress and dielectric displacement fields. They are defined as zero in thickness direction. The present shell element fulfills the important patch tests: the in-plane, bending and shear test. Some numerical examples demonstrate the applicability of the present piezoelectric shell element. *Keywords:* Mixed Field Variational Problem, Finite Element Formulation, Piezoelectricity, Smart Structures, Shells

A variational arbitrary Lagrangian–Eulerian finite-element formulation for standard dissipative solids at finite strains. **Jörn Mosler** (Ruhr-Universität Bochum, Germany), Michael Ortiz (California Institute of Technology, USA) GA/CT1665/004

A novel Arbitrary Lagrangian–Eulerian (ALE) finite element formulation for standard dissipative media at finite strains is presented. In contrast to previously published ALE approaches accounting for dissipative phenomena, the proposed scheme is fully variational. Consequently, no error estimates are necessary and thus, linearity of the problem and the corresponding Hilbert-space are not required. Hence, the resulting Variational Arbitrary Lagrangian-Eulerian (VALE) finite element method can

be applied to highly nonlinear phenomena as well. In case of standard dissipative solids, so-called variational constitutive updates provide a variational principle. Based on these updates, the deformation mapping follows from minimizing an incrementally defined (pseudo) potential, i.e., energy minimization is the overriding criterion that governs every aspect of the system. Therefore, it is natural to allow the variational principle to drive mesh adaption as well. Thus, in the present paper, the discretizations of the deformed as well as the undeformed configuration are optimized jointly by minimizing the respective incremental energy of the considered mechanical system.

Geometrical matrix of Timoshenko beam with nonlinear elastic supports. **Jerzy Rakowski** (Poznan University of Technology, Poland) GA/CT2000/004

The buckling analysis of a beam elastically supported on its ends including the shear-force effect is studied. The general case for the 4-dof beam element supported by springs with arbitrary linear and rotary stiffnesses is considered. The slope-deflection equations for E-B and Timoshenko beams are derived. The closed-form solution of these equations enables one to define stiffness and geometrical matrices for all kinematically and statically possible schemes of beams. The rigid-joint nodes correspond to the infinite-stiffness supports, the free displacement nodes correspond to the zero-stiffness spring supports.The investigations are extended for Timoshenko beams with nonlinear elastic supports. The reactions (forces and moments) are proportional to the third power of support displacements. The adequate slope-deflection equations are derived and the analytical solutions of these equations are given. The influence of support nonlinearity on the Timoshenko beam geometrical matrix and critical forces is analyzed and numerical parameter study is carried out.

The use of an hour-glass stabilized solid-shell finite element in forming simulations: theoretical aspects and first industrial applications. **Marco Schwarze** (TU Braunschweig, Germany), Stefanie Reese (TU Braunschweig, Germany) GA/CT3471/004

To obtain accurate results in finite element simulations of sheet metal forming processes classical three-dimensional solid elements with only displacement degrees-of-freedom have to be modified in the field of finite element technology. The goal is to eliminate the undesired effects of geometrical and material locking and to compute the sheet metal with only one element over the thickness.
One method to avoid locking in non-linear large deformation solid-shell formulations is the method of reduced integration, see e.g. [1-3]. The physically relevant deformation and stress response of the element is computed in a reduced number of Gauss points located on the shell director. To avoid the appearance of non-physical zero-energy modes an hourglass stabilization is necessary. The choice of these stabilization terms is still an object of research, in particular in the case of inelastic material behavior.
We compare the performance of the solid-shell formulation proposed in [1] in combination with different hourglass stabilizations. The goal is to develop an adaptive hourglass stabilization for which no additional user input is necessary. Numerical tests as well as industrial applications are presented.

GA/PP2166/004: **A coupled MD–FE approach for contact at microscopic length-scales.**

Presenter: Udo Nackenhorst (Leibniz Universität Hannover, Germany)
Co-author: Tobias Helmich (Universität Hannover, Germany)

A model for the electromechanical contact on a microscopic length-scale apparent in an atomic force microscope (AFM) is presented in this contribution. In contrast to classical contact on macroscale, the description on a microscopic length scale has to by physically motivated to ensure realistic simulation results. The contact is modeled by a Molecular Dynamics (MD) approach on a nanoscale with an analytical homogenization in physics. Here a potential formulation of the van der Waals force with a repulsive and attractive component is used for the interaction of two bodies resulting into a continuous contact description where normal– and tangential contributions are coupled consistently. The global system is modeled by a nonlinear Finite Element (FE) approach at the meso–lengthscale. The MD and FE methods are coupled directly by strong coupling via the weak form of the FEM. To encounter the multiscale problem a dimensional adaptive approach is used. Contact, continuum and beam elements, joined by transition elements with different degrees of freedom, are used for the efficient discretization. Numerical examples and results for the introduced coupling strategy are presented for typical AFM setups as fully 3D–simulations.

On wear-pattern generation in elastic systems. **Norbert Hoffmann** (TU Hamburg–Harburg, Germany) GA/CT2392/005

Many systems with moving contact show the appearance of regular wear patterns. Examples range from the generation of washboard patterns on dirt roads, to the polygonalization of railway wheels during operation, up to the appearance of thickness variations in the disks of disk brake systems. The origin of the wear patterns is generally thought to be found in the dynamical properties of the contact partners, like e.g. natural frequencies, modal damping, etc. The present work uses some elementary models to elucidate the fundamental mechanisms underlying the wear pattern generation. Two approaches to deal with the coupled structural and wear dynamics are presented. It turns out that wear pattern generation can be understood as an instability phenomenon of the surface evolution, coupled to the dynamical system. The role of structural characteristics, as well as some aspects of the wear model, are discussed. Finally an outlook is given how to extend the present modeling to technically relevant large-scale systems.

Ein Ansatz zur Beschreibung der dreidimensionalen Topographiedynamik bei Bremsvorgängen. **Michael Mueller** (TU Braunschweig, Germany), Georg Ostermeyer (TU Braunschweig, Germany) GA/CT1531/005

Die Dynamik in der Grenzschicht zwischen Bremsbelag und Bremsscheibe ist während eines Bremsvorganges durch eine komplexe Wechselwirkung zwischen Reibung und Verschleiß charakterisiert. Die extrem hohen lokalen Temperaturen, Drücke und die tribochemischen Prozesse führen zum Wachstum und der Zerstörung mesoskopischer, harter und dünner Strukturen auf der Oberfläche des Belages, sogenannter "Patches" [1].

Mit Hilfe eines dynamischen Reibgesetzes [1] und darauf aufbauend einem Modell eines Zellulären Automaten ist es prinzipiell möglich geworden, die Wirkung dieser Prozesse auf makroskopische Reibphänomene anzuwenden [2]. Um weiterhin explizite Aussagen über globale Verschleißraten oder laterale Anregungsmechanismen zu erhalten, ist dieses Modell auf eine dreidimensionale Topographiebe- schreibung erweitert worden.

Zur Verifizierung und Quantifizierung sind identische Bremssysteme mit unterschiedlicher Belastungsgeschichte (von eher gering bis hin zu extrem hoch) optisch untersucht worden. Die daraus gewonnenen Daten der Oberflächentopo- graphie und die Bestimmung charakterisierender Rauhigkeitswerte werden in diesem Paper den Ergebnissen aus der Simulation gegenübergestellt und interpretiert.

Evaluation of automotive disk brake noise behavior using piezoceramic actuators and sensors. **Stefan Schlagner** (TU Berlin, Germany), Utz von Wagner (TU Berlin, Germany) GA/CT2379/005

Brake squeal is a high-frequency noise of brake systems with frequencies from 1 up to 12 kHz. This noise does not affect the functionality of the brake. Nevertheless it is a serious comfort problem and it causes a high amount of costs to design a noiseless brake system.
The conventional method to evaluate the noise behavior of an automotive disk brake consists usually of realizing different operating conditions several times on a test rig and to measure an existing noise with respect to frequency and intensity by a microphone. This procedure takes a lot of time. The work to be presented shows that with the help of piezoceramic actuators and sensors the noise behaviour of the brake can be examined without making the brake squeal.

Experimentelle Untersuchungen von Stick-Slip-Schwingungen an Scheibenwischern. **Philipp Grönefeld** (Universität Hannover, Germany), Matthias Kröger (Universität Hannover, Germany) GA/CT1548/005

In Kraftfahrzeugen jeglicher Art werden Scheibenwischer zum Reinigen der Windschutzscheibe verwendet. Die Wischerblätter aus Gummi unterliegen dabei hohen Beanspruchungen durch Abgase, Sonneneinstrahlung, Verschmutzungen sowie Eis und Schnee. Die komplexe Reibcharakteristik des Materials führt nach gewissen Parameterzuständen aufgrund einer fallenden Reibkennlinie dazu, dass Stick-Slip-Schwingungen entstehen, die sich durch Rattern und Quietschen des Wischerblattes auf der Scheibe äußern und damit erhebliche Komfort- und Funktionseinbußen nach sich ziehen.

Mit Hilfe unterschiedlicher Prüfstände und Proben werden durch die Variation von Parametern wie Anpresskraft, Geschwindigkeit und Nässezustand verschiedene Belastungen simuliert und die entstehenden Schwingungen untersucht. Die so ermittelten Grenzzykel können Aufschluss über Möglichkeiten zur Optimierung der Wischerkonstruktion geben.

Influence of the non-linear contact stiffness on the vibration behaviour of a tyre tread block. **Matthias Kröger** (Universität Hannover, Germany), Patrick Moldenhauer (Universität Hannover, Germany), Gunnar Gäbel (Universität Hannover, Germany) GA/CT2291/005

In many technical applications, e.g. seals, belts and tyres, the contact of rubber elements influences the dynamical behaviour of the system. In the tyre/road contact friction depends on many parameters like relative velocity, roughness, normal pressure, temperature and material properties. The slip at high rolling speeds causes high-frequency deformations and vibrations.
Within the scope of this work the dynamic behaviour of a tyre tread block is described by a modularly designed model. Special emphasis is laid on the influence of the force-displacement characteristic between rubber and the rough surface. This characteristic is non-linear since at the beginning of the contact process only a small number of surface asperities interacts with the rubber. This leads to a declining contact stiffness characteristic with respect to the normal displacement. In the simulation the rough surface on which the tread block

slides is modelled as smooth with the friction characteristic of the respective material pairing and a non-linear description of the discussed local tyre/road interaction. This leads to an approximate description of the contact mechanics without losing numerical efficiency. Furthermore the model includes wear that changes the block geometry and thus the vibrational behaviour.
With the presented model of a tyre tread block dynamic effects like friction induced vibrations are simulated and compared with experiments conducted on a test rig.

On bending-torsion flutter of a cantilevered beam with tip jet . **J Wauer** (Universität Karlsruhe (TH), Germany) GA/CT1866/005

During the early seventies, several studies on the problem of dynamic instability of cantilevers under transverse follower forces by tip jet and the suppression of the increasing vibrations using feedback control were made. The investigations were based on a simplified geometrically nonlinear theory so that the derived boundary value problem might be imprecise. Some years later, the author presented the academic problem of lateral buckling of such a beam under follower moment tip load of constant magnitude based on a consistent geometrically nonlinear elasticity theory. To possibly improve the modeling of the first problem and to study alternative tip jet concepts, the cantilevered bar under non-conservative transverse fluid loading is re-considered here. In a first step, a consistantly formulated governing nonlinear boundary value is presented. The corresponding variational equations are derived next so that finally, the stability behavior can be analyzed. In addition to damping effects, the ratio of torsional and bending stiffness together with beam slenderness may influence the flutter load in a characteristic manner.

Application of history-dependent friction model to description of excited and self-excited vibration. **Roman Bogacz** (Institute of Fundamental Technological Research, Poland) GA/CT4287/005

In the paper a mechanical frictionally damped system subjected to harmonic excitation and mechanism of generation of stick-slip self-excited vibration is considered. Relatively complicated but piece-wise linear, history dependent friction model is used for description of the friction model. This model was experimentally identified. The friction force in the model depends on: velocity of relative motion, acceleration, sticking time (adhesion), and force rate. Such a friction model enables the description and the analysis of various cases of stationary and transient motion. That is why we can apply it also to the problem of an active control of self-excited mechanical systems. The other advantage of the modeling by the use of piecewise linear friction law is connected with an analytical form of the solution obtained for each linear part of the characteristic. The paper deals mainly with the problem of frictionally-excited vibration of the system, but also reduction or amplification of vibration by means of an additional external excitation of the system with friction will be studied. The system used for verification of the model is composed of an elastically suspended lumped mass made of steel which interacts frictionally with the belt made of composite material. The system additionally can be subjected to a periodic excitation through an elastic element. The simultaneous self-excitation and external periodic force results in occurrence of the solution in the form of one - and higher periodic vibration, quasi - periodic as well as non - periodic (chaotic) oscillation. Results of simulation of some interesting cases will be presented. For example, a case when frictionally self-excited stick-slip vibration are additionally influenced by an external harmonic excitation than for the particular choice of amplitude and frequency of the external excitation it is possible to minimise the amplitude of oscillations more than two times. For majority of parameter values of the external excitation, the amplitude of the system motion is greater then without it. The discussion of appropriate choice of the parameters is given in the paper.

Oscillatory instabilities due to friction. **Hartmut Hetzler** (Universität Karlsruhe (TH), Germany) GA/CT1194/005

Regarding self-excited frictional oscillations, one key issue is to understand the mechanism which triggers the vibrations. Among the most important mechanisms in that context are the so-called "negative damping", leading to divergence instability, and the influence of circulatory forces, which may cause oscillatory instabilies ("flutter"). Over he last decades, the latter effect has been subject of intensive research, revealing the pecularities of circulatory systems. Within this contribution, basic properties of circulatory systems shall be addressed in the context of friction-induced vibrations. Among others, the relation between complex eigenvectors and stability will be discussed as well as the influence of structural damping.

Friction-induced vibrations in a plate/disk. **Gottfried Spelsberg-Korspeter** (TU Darmstadt, Germany) GA/CT2130/005

This paper considers a rotating Kirchhoff plate in contact with two elastic pads. Friction occurs between the disk making the system susceptible for self-excited vibrations. Using the principle of virtual work and the kinematic assumptions from Kirchhoff plate theory the boundary value problem is derived from the basics of the theory of elasticity. Special attention is given to the coupling of disk and plate equations. It is shown that the coupling depends on the interaction between plate and pads and on the assumptions made for the deformation gradient. The insights gained directly from the equations of motion are compared to the results obtained by a Ritz discretization approach. In particular the problem of considering point contact between plate and pads in the continuous approach is addressed.

The results obtained can be used for modelling frictionally self-excited vibrations of disks. They might help to clarify the influence of in-plane modes of the disk on the occurrence of squeal.

The Earth is double system. **Dmitry Kiryan** (Institute of Problems of Mechanical Engineering RAS, Russian Federation) GA/CT3880/001

The Earth's rotation axis moves parallel to itself without changing the angle of inclination to the ecliptic plane. The translational motion of the Earth's axis of rotation is caused by the motion of the Earth's center of mass in the Earth's body. The motion of the Earth's center of mass in space is due to the motion of the consistent inner core of the Earth in the liquid outer core under the action of the total (internal and external) gravitational field. The comparison of our calculations and observational data on variations in "latitudes" of places and acceleration of gravity has shown that they are in good agreement. Our model has been shown to adequately describe the physical process of motion of the Earth's centre of mass inside the Earth's body.

Analysis of the vibration behavior of the Dobson space telescope. **Kerstin Kracht** (TU Berlin, Germany), Utz von Wagner (TU Berlin, Germany), Ulrik Strehlau (TU Berlin, Germany) GA/CT2357/005

The Dobson Space Telescope is a research project of TU Berlin. Aim of the project is to develop a new type deployable space telescope that can overcome the mass and volume limitations of cost effective micro satellites. Due to the deployable structure of the telescope there are two basic questions referring to mechanical vibrations. Firstly, what is the behaviour of the folded structure during launch? Secondly, do the vibrations of the deployed telescope allow the production of high quality photos?

The author has analyzed the vibration behavior of the Dobson Space Telescope. This paper gives an overview about the results of the metrological modal analysis and of analytical and numerical calculations. All results show that the aluminium lab model of the telescope would be ready for service referring to the aspect of mechanical vibrations.

Coupled nonlinear oscillations in compressed thin-walled bars. **Arkadiy Manevich** (Dnipropetrovs'k National University, Ukraine) GA/CT2615/005

In thin-walled bars the spectrum of short-wave local modes is usually rather dense, and natural frequencies for overall and some local modes can be commensurable: their ratio can be close to 1:1, 2:1 and so on. Under action of axial force the external parametrical resonance may take place simultaneously with internal resonances of various types, such as one-to-one resonance, auto-parametrical or combination resonance. In the paper the nonlinear oscillations in thin-walled bars caused by the compressive and harmonic axial forces are studied with taking into account the interaction of overall and local modes. It is assumed that the bar has one axis of symmetry, and the natural frequencies for the overall mode and certain local mode are close. Equations of motion are derived based on assumption that the natural modes of oscillations coincide with the buckling modes (it is the case, in particular, for simply supported bars). The dynamic displacements field is expanded in a series in natural buckling modes (the KoiterŠs type expansion for the static buckling problem). The equations of motion in the first nonlinear approximation comprise quadratic nonlinearities due to interaction of the modes. These equations have been solved by the multiple scale method. Equations of amplitudeŰfrequency modulation have been obtained and analysed. It is shown that the interaction of the external parametric and internal resonances gives rise to complex nonlinear phenomena. The energy exchange between different modes can lead to appearance of new steadyŰstate coupled oscillations and coupled non-stationary oscillations. Such a complicated behavior can cause loss of stability in certain mode because of accumulation of energy on this mode.

Analysis of the stator/rotor-contact in a two-stators hybrid-transducer-type ultrasonic motor. **Nantawatana Weerayuth** (Universität Karlsruhe, Germany), Wolfgang Seemann (Universität Karlsruhe, Germany) GA/CT2260/005

In this paper, a new procedure to understand the contact mechanism of an ultrasonic motor by using finite-element analysis is presented. First, the modes of vibration of a stator will be calculated and be analysed using a commercial finite element program package ANSYS. The distribution of elliptic path of motion of nodes on the stator surface is studied. The computed resonance frequencies of the stator are compared with the measured one by using the precision impedance analyzer AGILENT 4294A. Finally, the contact conditions, normal displacement, normal velocity, tangential velocity and friction force between stator and rotor will be calculated.

Modellierung der Schwingungen beim Werkzeugschleifen. **Lars Panning** (Leibniz Universität Hannover, Germany), Matthias Kröger (Universität Hannover, Germany) GA/CT1984/005

Die Fertigung von Bohrern und Schaftfräsern aus Hartmetall oder Schnellarbeitsstahl (HSS) erfolgt aufgrund der großen Härte der Werkstücke häufig durch Profilschleifprozesse mit Diamant- oder CBN-Schleifscheiben. Aufgrund der Wechselwirkung zwischen Werkstück, Schleifscheibe und Prozess kommt es während der Erzeugung der Spannuten zu Werkstückschwingungen, die zu unerwünschten Fertigungsungenauigkeiten und Formfehlern führen. Ziel ist es, mit Hilfe von Simulationen kritische Prozessparameter zu ermitteln, bei denen z.B. durch regeneratives Rattern instabile Zustände auftreten. Diese können die Werkstückqualität erheblich reduzieren.

Es wird ein Simulationsmodell vorgestellt, das den beim Werkzeugschleifen hohen Materialabtrag und die statischen und dynamischen Nachgiebigkeiten des weit auskragenden, schlanken Werkstücks berücksichtigt. Insbesondere wird die sich während des Prozesses stark ändernde Masse und Steifigkeit des Werkstücks betrachtet und in ein mechanisches Ersatzmodell umgesetzt. Die Kopplung zwischen Schleifscheibe und Werkstück erfolgt über ein Prozessmodell, das diskrete, in der ausgedehnten räumlichen Kontaktzone auftretende Prozesskräfte berücksichtigt. Hierzu wird die Eingriffsgeometrie in jedem Zeitschritt unter dem Einfluss dynamischer Relativverlagerungen ermittelt und das Zerspanvolumen in radialer, axialer und in Umfangsrichtung diskretisiert. Anschließend werden die Prozesskräfte in Abhängigkeit der diskreten Volumina ermittelt. Unter Berücksichtigung der momentanen dynamischen Eigenschaften des Werkstücks können nach erfolgter Kopplung des Struktur- und Prozessmodells kritische Bearbeitungszustände detektiert werden, deren Vorhersage und Vermeidung für die Erzeugung qualitativ hochwertiger Werkstücke unerlässlich ist.

Modeling of jointed structures using zero thickness interface elements. **Johannes Geisler** (Universität Erlangen-Nürnberg, Germany), Kai Willner (Universität Erlangen-Nürnberg, Germany) GA/CT2185/004

An important contribution to global damping of mechanical devices is *structural damping* in joint interfaces. The mechanism of structural damping is energy dissipation due to frictional effects in contact areas of joints. In order to investigate the mechanical behaviour in joint interfaces numerically, a contact element in the context of the Finite Element Method (FEM) is presented. The suggested element is an isoparametric zero thickness element which is well suited for the present problem because the contact area is known and only small relative displacements occur.

In these elements arbitrary linear or nonlinear constitutive contact models for normal and tangential contact behaviour can be implemented. Using a proper parametrisation of the contact

area, it is possible to apply the element in contact interfaces lying arbitrarily in space and in interfaces discretized with distorted elements.

In joint interfaces it is undesirable that gross slip occurs, i.e. only mircroslip effects take place. So the constitutive element formulation has to be able to model these effects properly. Different numerical examples are shown and compared with experimental results.

Modelling of rotating shafts with flexible disks. **Jakub Šašek** (University of West Bohemia, Czech Republic), Vladimír Zeman (University of West Bohemia, Czech Republic), Michal Hajžman (University of West Bohemia, Czech Republic) GA/CT1922/005

The dynamic analysis of high-speed drives and their operation conditions call to more complex mathematical models, for which it is needed to develop new modelling approaches. The vibration analysis of driving mechanisms is commonly performed with the assumption of ideal rigid disks mounted on flexible shafts. However, there are cases in which the vibration of disks become important and the rigid body assumption is too rough for detailed dynamic analysis. This assumption is not correct in the case of the high frequency excitation and therefore it is necessary to care about special approaches to the modelling of rotating shafts with flexible disks. There are no difficulty in modelling rotors using standard commercial FEM tools, but such codes usually do not take into account the all effects caused by the rotation.

This paper deals with the methodology of the modelling of rotating shafts with flexible disks. Rotating shafts are modelled as a one dimensional continuum on the basis of the Bernouli-Euler theory, which assumes that the shaft cross section remains a flat plane and is perpendicular to the centerline during vibration. Disks are modelled as a three dimensional continuum by means of the finite element method. The presented approach allows to introduce centrifugal and gyroscopic effects. The special coupling matrix is used for connecting the rotating shaft and mounted flexible disk.

Because vibration analysis of gear-shaft-bearing systems is a very important part of rotor dynamics, the gear connection matrix between two flexible wheels mounted on the particular shafts is also developed and presented in the paper. The whole flexible geared-disk-shaft-bearing system is fixed to the rigid frame by the rolling element bearings. The proposed modelling methodology is used in the example of the simple system composed of two coupled shafts with gears.

On conditions of flutter onset for elongated plate in supersonic gas flow. **Boris Loginov** (Ulyanovsk State University, Russian Federation), Oleg Makeev (Ulyanovsk State University, Russian Federation) GA/CT1787/005

The considered problem is described by the nonlinear equation [1]

$$\frac{\gamma}{g}\frac{\partial^2 w}{\partial t}+\varepsilon\frac{\partial w}{\partial t}+\frac{D}{h}\frac{\mathrm{d}^2}{\mathrm{d}x^2}\left(\frac{w''}{(1+w'^2)^{3/2}}\right)=\frac{1}{h}p_0\mathcal{K}(w',M,\gamma)+\frac{Eh}{a(1-\nu^2)}w''\int_0^a[(1+w'^2)^{1/2}-1]\mathrm{d}x \qquad (1)$$

for two types of boundary conditions I. $w(0,t)=0$, $w''_{xx}(0,t)=0$, $w(a,t)=0$, $w''_{xx}(a,t)=0$ (hingely fastened edges); II. $w(0,t)=0$, $w'_x(0,t)=0$, $w(a,t)=0$, $w'_x(a,t)=0$ (both edges are rigidly fixed), where w is the deflection of the plate, h – its thickness, a – its width, $D=\frac{Eh^2}{12(1-\nu^2)}$ the stiffness, E the Young module, ν is the Poisson coefficient, ε the linear damping coefficient, γ is the density of the plate; M is the Mach number, p_0 – the pressure and γ – the polytropic exponent, g – the acceleration of gravity; $\mathcal{K}(w',M,\gamma)$ is nonlinear differential operator describing the aerodynamic action.

According to Lyapounov-Schmidt method for dynamic bifurcation [2] the linearized equation (1) in dimensionless variables is reduced to the problem $u^{(4)}(x)+\sigma u^{(1)}(x)-\alpha^2\frac{A}{\chi^2}=0$ for complex-valued function $u(x)$ with boundary conditions of the type I and II ($a=1$, σ is proportional to M). It is shown that the boundary condition determinants have simple roots and the rank of the relevant matrices is equal to 3. Consequently the existence of oscillatory solutions for the problem (1) is equivalent to the existence of simple pure imaginary eigenvalues $\pm i\alpha$.

Dynamic stability of disks subjected to rotating in-plane edge loads. **Tyau-Her Young** (National Taiwan University) GA/CT4036/005

The vibration and stability behavior of a spinning disk under a space-fixed in-plane edge load have attracted researchersŠ attention because of its potential application in such fields as spur gear transmission, grind wheel operation and circular saw cutting. But the presence of the initial stress and the Coriolis force that arise due to the rotation of the disk and the presence of the initial stress due to the in-plane edge load which has relative motion with respect to the disk make the problem quite complicated. Therefore, this problem is sometimes simplified by either neglecting the rotation effect of the disk or neglecting the relative motion between the load and the disk.

This paper studies the dynamic stability of a stationary annular plate subjected to a static in-plane edge force moving around the circumference of the disk with a constant speed. Due to this rotating in-plane edge load, the stress field is a periodic function of time, and parametric excitation is observed in the equation of motion when the analysis is conducted in an inertial coordinate system. First the rotating in-plane edge load is expanded into a Fourier series. Next a stress analysis is carried out to determine the initial stress distributions caused by the rotating edge load. Then the finite element method is applied to yield the discretized equations of motion. Finally, the method of multiple scales is adopted to derive the stability boundaries of the disk.

Numerical results show that if the rotating in-plane edge load has a tangential component, there exists a critical damping factor below which the disk is unstable no matter what rotating speed the in-plane edge load is. For disks with a damping heavier than the critical damping factor, combination resonance of the summed type , where is the rotating speed of the in-plane edge load, and are the pth and qth natural frequencies of the disk, may exist, but not combination resonance of the difference type.

Stability analysis of non-conservative mechanical systems via optimization. **Nils Wagner** (Universität Stuttgart, Germany) GA/CT979/005

The generalized eigenvalue problem $K x = \lambda M x$, where K and M are $n \times n$ real matrices with M being symmetric positive definite, arises in many applications, most notably in structural dynamics. A major difficulty is the stability analysis of such systems, when the matrices are parameter dependent. Since the stiffness matrix K is nonsymmetric the pencil (K, M) is known to admit complex eigenvalues.

Nowadays, these matrices are large, sparse and only a few of the eigenvalues and the associated eigenvectors are desired.

Following Auchmuty several objective functions are used to solve the eigenproblem via (unconstrained) optimization. Finally, a numerical algorithm is proposed for computing an arbitrary eigenpair of the matrix pencil. Knowledge of (K, M) is only required through a routine that performs matrix-vector products.

Hopf bifurcations of travelling waves in a brake-like system. **Alois Steindl** (TU Wien, Austria) GA/CT1874/005

We consider a system composed of an elastic tube, which is fixed at the outer boundary and in frictional contact with a rigid cylinder, rotating inside the tube about the common axis. Under the assumption of Coulomb's friction law at the contact surface between the two bodies several types of rotating slip-stick and also slip-stick-separation travelling waves with different wave numbers can be observed.

For a wide range of parameters the linearized system has unstable complex eigenvalues, which cause high frequency oscillations and unpleasant squeal. We try to locate the stability boundaries in parameter space and determine the oscillatory motion in the unstable regime.

Analysis of the effect of bending stiffness on slender continua in stationary motion. **Ulrike Zwiers** (Universität Duisburg-Essen, Germany) GA/CT2103/005

Studies concerned with the dynamics of belt-drive systems are commonly based on either second-order string models or fourth-order beam models. While the former exhibit non-dispersive wave propagation, the latter possess both propagating and non-propagating waves due to the dispersive nature of flexurally stiff continua.

This talk addresses the transition from perfect flexibility to flexural rigidity. First, the problem of stationary motion is defined, and it is demonstrated that a perfectly flexible string can undergo a snake-like motion, that is, a motion along an arbitrary fixed path in space only at constant speed. Furthermore, the geometric shape of a flexurally stiff continuum in stationary motion is shown to coincide with the static shape. For the special case of motion along a straight line, the linear equations of motion governing the transverse vibrations of a flexurally stiff continuum in axial motion are obtained by superposing small perturbations on the stationary solution. Referring to a belt drive as a typical application of the problem, the definition of appropriate boundary conditions is briefly discussed and the closed-form solutions of the corresponding boundary-value problems are presented. The natural frequencies are determined by applying the phase-closure principle which provides further insight into the wave propagation in axially moving continua.

On the nontrivial interaction of strongly-damped mechanical systems with high-frequency excitation. **Alexander Fidlin** (LuK GmbH & Co. oHG, Bühl, Germany) GA/CT2234/005

Nontrivial effects of high-frequency excitation on mechanical systems have been investigated intensively in the last decade. However, the main attention is normally paid to weakly damped systems which are usual in mechanical applications. In that case the strong high-frequency excitation terms are balanced with large inertial forces (i.e. acceleration terms which are proportional to the frequency square). There are at least two research and applications areas where the situation is significantly different. It is quite usual to apply strong damping to control systems. The reason for that is the objective to avoid unnecessary oscillations and to lead the controlled system for example to its final position as soon as possible. Fast vibrations are often used in control systems either in form of vibrational control or in order to smoothen the effective dry friction. The interaction of this fast excitation (if it is sufficiently strong) with strong damping terms can cause undesired phenomena irritating the control system. Another and perhaps even more important area are micro systems. It is almost obvious that inertial terms are proportional to the mass of the system, i.e. to the cube of its linear dimension. The damping forces are usually applied to the surface of the body. Thus they have to be proportional to the square of the linear dimension. Decreasing linear dimension increases the importance of the damping terms. This paper investigates nontrivial effects occurring if a strongly damped mechanical system is subjected to strong high-frequency excitation. The analysis is focused on the differences between the classic results well known for weakly damped systems and new effects for which the large damping terms are responsible.

Codimension-1 bifurcations of a friction oscillator. **Andreas Teufel** (TU Wien, Austria), Hans Troger (TU Wien, Austria), Alois Steindl (TU Wien, Austria) GA/CT2333/005

In [1] the complete list of all codimension-1 (1-parameter) bifurcations for discontinuous planar piecewise smooth autonomous systems, which are called Filippov systems, is given. By means of the standard model of the friction oscillator, where a mass which is elastically supported is in frictional contact with a rough moving belt, we study for increasing the speed of the moving belt the sequence of qualitative changes in the phase plane. This will be done in a systematical way by comparison with the classification in [1] for different parameter combinations in a three parameter law of the friction force depending on the relative velocity.

Further we show for a more complicated (infinite dimensional) friction system, i.e., a rigid shaft rotating with frictional contact in a space fixed elastic tube that due to the more complicated mechanical model already for simpler friction laws similar effects are possible as for the simpler mechanical model with more complicated friction law.

Gyroscopic stabilization and destabilization in non-conservative systems. **Oleg Kirillov** (Lomonosov Moscow State University, Russian Federation) GA/CT496/005

Stability of a linear autonomous non-conservative system in presence of potential, gyroscopic, dissipative, and non-conservative positional forces is studied. The cases when the non-conservative system is close to a gyroscopic system or to a circulatory one, are examined. It is known that the marginal stability of gyroscopic and circulatory systems can be destroyed or improved up to asymptotic stability due to action of small non-conservative positional and velocity-dependent

forces. The present contribution shows that in both cases the boundary of the asymptotic stability domain of the perturbed system possesses singularities such as "Dihedral angle" and "Whitney umbrella" that govern stabilization and destabilization. Approximations of the stability boundary near the singularities and estimates of the critical gyroscopic and circulatory parameters are found in analytic form. In case of two degrees of freedom these estimates are obtained in terms of the invariants of matrices of the system. As an example, the asymptotic stability domain of the modified Maxwell-Bloch equations is investigated with an application to the stability problems of gyroscopic systems with stationary and rotating damping, such as the Crandall gyropendulum, tippe top and Jellet's egg.

On the extension of Brommundt's solution to the Painlevé paradox. **Florian Fischer** (TU Darmstadt, Germany) GA/CT2774/005

Painlevé's paradox for dry friction was formulated in 1895 and deals with the contradiction appearing in a rigid, inhomogeneous cylinder rolling on a rigid and rough surface. An analysis based exclusively on rigid body dynamics results in singularities and abnormal values for the contact forces. Recently (2003) Brommundt has shown that introducing elasticity in the normal direction and adding an additional degree of freedom leads to the resolution of the paradox and to vibrations of high frequency in the normal direction. This note extends Brommundt's approach to multiple, discrete and elastic bodies interacting by a stiff coupling. From the equations of motion it can be seen that self-excited vibrations occur. The results can be used to resolve inconsistencies arising in multi-body codes.

On the dynamics of a nonlinear rotor-floating ring bearing system. **Aydin Boyaci** (Universität Karlsruhe (TH), Germany), Carsten Proppe (Universität Karlsruhe, Germany), Wolfgang Seemann (Universität Karlsruhe, Germany) GA/CT2353/005

Today, in high speed applications the rotors are commonly supported by hydrodynamic journal bearings. One typical configuration of journal bearings incorporated in automotive turbochargers is the floating ring bearing. Rotors supported by floating ring bearings have many advantages for example with regard to costs and power consumption. However, they might become unstable with increasing speed of rotation. At the onset of instability both the perfectly balanced and unbalanced rotor undergoes self-excited vibrations which could cause the mechanical breakdown of the system. This phenomenon of *oil whip* is very well known from the investigations of the plain journal bearing occurs here in a different form. At the stability limit the rotor begins either oscillating with about the half of the ring speed or the half of the ring speed plus the half of the journal speed depending on the system parameters.

For this reason a rotor-floating ring bearing model is presented showing the mentioned characteristics. By applying the nonlinear equations of motion the limit cycles of the system are determined and its loss of stability is investigated. Furthermore, the influence of the rotor-bearing design parameters on the stability of the system is discussed.

Influence of internal parametric and kinematic gearing excitation on nonlinear gearbox vibration. **Miroslav Byrtus** (University of West Bohemia, Czech Republic), Vladimír Zeman (University of West Bohemia, Czech Republic) GA/CT1892/005

The mathematical modelling of nonlinear gearbox vibration is based on the system decomposition into linear subsystems (shafts with gears and a housing) and on discretization of nonlinear couplings between subsystems. The final condensed mathematical model is created by means of spectral and modal submatrices corresponding to the lower vibration mode shapes of the mutually uncoupled and undamped subsystems.

The rotating shafts are joined mutually by gear couplings and are linked up by rolling-elements bearings with the housing. The bearing model respects real number of rolling bodies and real roller nonlinear contact forces acting between journals and the outer housing in dependance on their deflection. The nonlinear gearing model enables to consider such vibration, when in consequence of low static load and internal excitation generated in gear meshing, the gear motion is characterized by the gear mesh interruption. Therefore vibrations are accompanied by impact motions, bifurcation of solution and chaotic motions. We consider two main excitation sources, the internal kinematic excitation in gearing caused by kinematic transmission errors and the parametric excitation caused by periodic change of m and $m+1$ teeth in gear meshing. Because of this change the meshing stiffness is described by a time varying function, whose accurate evaluation can be performed by using the theories proposed by many authors.

The influence of simultaneous internal kinematic and parametric excitation is investigated for different levels of external static loading of the gearbox in dependance on revolutions of the driving shaft.

The gear drive motions are explained by applying time-integration method to the condensed model by means of phase trajectories of gearing and bearing deformations. The presented approach to the nonlinear vibration analysis of the large multibody gear drives is illustrated on a real car gearbox.

Dynamics of space systems with pendular elements. **Alexander Burov** (Russian Academy of Sciences, Moscow) GA/CT2252/005

Dynamics of Orbital Systems with pendular elements is a subject of intensive investigations, in particular, within the frame of the programme of creation of Orbital Tethered Systems and Terrestrial and Lunar Space Elevators. In the talk one discusses the problems of existence and stability of steady configurations of Space Pendula within the various assumptions, as well as regular and chaotic dynamics of Space Pendula subjected to periodic excitations.

Model of the axial load of the band-saw. **Jozef Wojnarowski** (Silesian University of Technology, Gliwice, Poland) GA/CT3704/005

The paper presents a model of load exerted on the self-aligning head of a cutting machine. The formulated model concerns the proper conditions of exploitation of the cutting machine, preventing of slips of the saw on the wheels. The endless band-saw is spread between two wheels, after which the tension recommended by the producer is applied. The tension is expressed in units of the mean tension in the saw: for metal-cutting saws it has been assumed within the range of 200-250 MPa. Depending on the type of the cutting machine, the band-saw is twisted in the cutting zone by means of two guides 4, 8 at a constant angle, generally not exceeding 900 (Fig.1). The guides facilitate the attainment of the pre-set geometrical properties of the surface at the kerf. The maximum value of the axial load exerted on the saw occurs at its contact with the driving wheel. The diagram is based on the assumption that the applied values of the forces do not change with time. Ac-

tually, this does not fully comply with reality. The first reason for this are the vibrations in the driving system. The second reason, implicating the former one, is the continuous getting in mesh and out of mesh of the subsequent teeth in the cutting zone. In order to investigate the character and progress of changes of the impulsive cutting force a device with dynamic force sensors has been designed and constructed, installed in vice. This device, , permits to measure the impulsive load Pz transmitted to the device in cutting zone of the saw teeth The analysis of the obtained results has shown that the spectrum of the measured force contains a component which is specific for the applied pitch of the saw and its speed, which value depends on the loading of the teeth and can be used for the automatic control of the instantaneous value of the pressure force of the saw exerted on the object 6that is being cut, depending on the changing conditions of cutting. Experimental investigations have shown that the application of the measurement system (which measures cutting force) allows to adjust the pressure force of the bandsaw on a workpiece. The adjustment strategy takes into account the current cutting parameters, e.g. by detecting the characteristic components of the spectrum of force.

Investigations on the wire-slicing process. **Thomas Liedke** (TU Bergakademie Freiberg, Germany), Alfons Ams (TU Bergakademie Freiberg, Germany) GA/CT3778/005

The wire slicing technology plays an important role on the manufacturing of thin discs out of brittle materials and is used for example in the solar- and microchip industry. The surface of a wire sliced disc shows a characteristic geometry, which suggest the influence of oscillations in the slicing process. In order to examine the process a distinct-element-model is used to simulate the motion and the interaction of the slicing-particles with the moving wire and the workpiece. The simulation shows interesting phenomena like clustering of particles and reacting forces to the wire, which could be one reason for the observed oscillation in the process.

Partial differential–algebraic equations for simulating frequency-modulated signals. **Roland Pulch** (Bergische Universität Wuppertal, Germany) GA/CT4251/005

In radio frequency applications, signals with widely-separated time scales arise in electric circuits. For example, the amplitude and/or frequency of fast oscillations is changed by slowly varying signals. A multidimensional modelling of these signals allows for an alternative approach in a numerical simulation, since the time scales are decoupled. The representation of frequency modulated signals leads to warped multirate partial differential algebraic equations. Initial-boundary value problems or biperiodic boundary value problems have to be solved according to the underlying periodicities in the signals. Moreover, the adequate determination of an arising local frequency function is crucial for the efficiency of the model. We present strategies based on minimisation criteria to identify a suitable local frequency function. Numerical simulations using the resulting conditions are performed.

Stochastic oscillations in circuit simulation. **Thorsten Sickenberger** (Humboldt-Universität zu Berlin, Germany), Renate Winkler (Humboldt-Universität zu Berlin, Germany) GA/CT4111/005

Due to parasitic effects in integrated circuits it becomes desirable to take noisy elements into account. As a consequence the underlying circuit equations are extended by an additional stochastic part, which extends the differential-algebraic equation (DAE) to a stochastic differential-algebraic equation (SDAE).
We present an adaptive simulation method for an ensemble of solution paths, which is computed simultaneously. The control strategy is based on estimating the time-discretization and the sampling error during the numerical integration. This approach provides a framework for efficient transient noise analysis of oscillatory circuits as well as of non-oscillatory circuits.

Finally we will illustrate the results of the simulation of some real-life problems and show their different behaviour in a noisy environment.

On the influence of crosswind on the overturning stability of railway vehicles. **Christian Wetzel** (Universität Karlsruhe, Germany), Carsten Proppe (Universität Karlsruhe, Germany), Claire Yalamas (Universität Karlsruhe, Germany) GA/CT1189/005

In recent years modern railway vehicle design shows a trend to faster, lighter and more energy efficient railway systems. These developments unfortunately alter the crosswind stability in a negative manner and so the risk of overturning of railway vehicles during operation in strong winds becomes a critical issue. The risk of overturning is quantified by the probability that a railway vehicle capsizes. To improve the crosswind stability it is very important to know the influence of the design and excitation variables on the wheel unloading of the railway car. The wheel unloadings of the windward wheels are the most critical factors. Sensitivities of the design and excitation variables with respect to the probability of failure are calculated and the most influential variables are accentuated. To get a deeper insight of the behavior of the railway system it is essential to model the railway vehicle and the environment as realistic as possible. This means that especially the wind excitation has to be modeled very precisely taking the turbulent fluctuations and track irregularities into account. In this talk results of the mentioned investigations are shown.

A proof of Mikota's conjecture. **Wolfgang Weber** (TU Dresden, Germany) GA/CT5053/005

In 2001 Mikota designed a chain structured mass–spring vibration system with n degrees of freedom. Mikota developed special distributions for spring stiffnesses k_i and masses m_i, each coupled to n and the coordinate x_i. Furthermore the k_i are depending on a basis-stiffness k as the masses m_i depend on a basis-mass m. According to Mikota this arrangement leads to natural frequencies $\Omega_i = i\Omega$ whereas $i = 1, \ldots, n$ and $\Omega = \sqrt{k/m}$. The presentation will prove the aforementioned supposition.

Finite thermo-viscoplasticity of amorphous glassy polymers: experiments, modeling and simulations. **Serdar Göktepe** (Universität Stuttgart, Germany), Joel Méndez (Universität Stuttgart, Germany), Christian Miehe (Universität Stuttgart, Germany) GA/CT4005/006

The contribution is concerned with experimental procedures, constitutive modeling and the algorithmic implementation of thermomechanical coupling effects in rate-dependent finite plasticity of glassy polymers. The experimental investigations involve both homogeneous and inhomogeneous tests at varying temperature levels. The true stress-strain curves obtained from homogeneous uniaxial and plane strain compression experiments are employed for the identification of the adjustable parameters in the proposed three dimensional constitutive model. In addition to load-displacement curves obtained from inhomogeneous experiments, non-uniform distributions of deformation fields are presented, such as thickness changes along a dumbbell-shaped specimen. The facility employed for the optical measurement of the deformation fields is equipped with CCD cameras and a post-processing software. In contrast to the existing kinematic approaches to finite plasticity of glassy polymers, we propose a distinct kinematic framework constructed in the logarithmic strain space. The logarithmic framework is extremely attractive due to the fact that it allows a very efficient algorithmic treatment of the finite plasticity akin to geometrically linear theory. The evolution law of plastic strains is adopted from Arrhenius-type rate formulations that are based on the one-dimensional micromechanically motivated approaches. The proposed formulation is algorithmically implemented and used for finite element analyses of three-dimensional boundary value problems. The model parameters determined from homogeneous experiments are further validated by simulating the inhomogeneous experimental data involving the optical field measurements.

Vergleichende Messungen und Simulationen annähernd homogener Belastungsverteilungen. **Carsten Hohl** (Universität Hannover, Germany), Thomas Alshuth (Deutsches Institut für Kautschuktechnologie, Germany), Jörn Ihlemann (Deutsches Institut für Kautschuktechnologie, Germany) GA/CT3682/006

Zur Charakterisierung und Prüfung technischer Gummiwerkstoffe werden häufig Messmethoden herangezogen, deren Ziel die Erfassung einer möglichst homogenen Verteilung von Spannungen und Verzerrungen ist. Die am besten bekannte und bei weitem am häufigsten durchgeführte Messmethode dieser Art ist die Zugbelastung von S2-Probekörpern. Diese Probekörper weisen zwischen den beiden für die Einspannung vorgesehenen Enden einen schlanken prismatischen Mittelteil auf, in dem sich bei der Belastung eine weitgehend homogene einachsige Belastung einstellt. Diese Belastung wird durch die aufgebrachte Gesamtkraft und die unmittelbar am Mittelteil gemessene Längung erfaßt. Weitere Beispiele für Standardmessmethoden sind kombinierte Zug- / Druckversuche an rotationssymmetrischen Hantelprüfkörpern, Druckversuche an zylindrischen Prüfkörpern sowie mehrachsige Zug- und einfache Scherbelastungen.

In einigen dieser Fälle werden mit unterschiedlichen Messmethoden die gleichen Belastungsarten erzeugt. Darüber hinaus ergeben sich aus der annähernd vollständigen Inkompressibilität der Gummiwerkstoffe weitere Vergleichsmöglichkeiten. Beispielsweise sollten im Idealfall bei einer äquibiaxialen Zugbelastung und beim einachsigen Druckversuch identische Verzerrungszustände erzielt werden. Die gemessenen Spannungen sollten sich dementsprechend durch eine Umrechnung des hydrostatischen Drucks ineinander umrechnen lassen.

Abweichungen von den prinzipiell zu erwartenden Übereinstimmungen erklären sich zum Teil aus Unterschieden in den Materialeigenschaften, die aus der Vulkanisation unterschiedlicher Geometrien herrühren können. Neben eigentlichen Messfehlern kommen Abweichungen von der homogenen Spannungs- / Verzerrungsverteilung in den vermessenen Materialbereichen als weitere Erklärungen für Abweichungen von den theoretischen Erwartungen in Frage. Der Grad der in den verschiedenen Messmethoden erreichten Homogenität läßt sich durch FEM-Simulationen der realisierten Belastungen unter Einsatz geeigneter Stoffgesetze erfassen. Gleichzeitig stellt ein breites Testprogramm unterschiedlicher Belastungsarten am gleichen Material eine weitreichende Möglichkeit zur Beurteilung der Anpassbarkeit und damit der Praxistauglichkeit der verwendeten Stoffgesetze dar.

Experimental and numerical investigations of a compressible cellular rubber. **Michael Johlitz** (Universität des Saarlandes, Germany), Holger Steeb (Universität des Saarlandes, Germany), Stefan Diebels (Universität des Saarlandes, Germany) GA/CT3625/006

Cellular rubbers are multifarious used in the automobile industry; e.g. in the construction of gaskets for doors and windscreens. Accordingly they play an important role not only in the mentioned branch. In this contribution, we investigate a compressible cellular rubber in an uniaxial tension test under quasi-static and isothermal conditions. From the modelling site, we introduce a continuum mechanical material model on the basis of the theory of porous media which is able to describe the complex compressible material behaviour of the tested specimen. The established material parameters are identified by a biologic evolution strategy method and the simulations are compared with the obtained experimental results.

Application of Rosenbrock-type methods to a constitutive model of polymeric material. **Ahmad-Wahadj Hamkar** (Universität Kassel, Germany), Stefan Hartmann (Universität Kassel, Germany) GA/CT2384/006

Polymeric materials show a pronounced time dependent material behaviour like relaxation and creep. In the case of polyoxymethylene this is also combined with a tension-compression asymmetry. Furthermore, there are indications of remaining deformations so that a constitutive model of viscoplasticity is an appropriate choice. Overstress-type models have an additional advantage in view of there modular structure whereas a yield-function free concept is more suitable. Based on a constitutive model presented in [1] the structured behaviour of parts has to be computed. Commonly, iteration-based implicit finite element computations are applied. In this lecture, linear-implicit Runge-Kutta methods (Rosenbrock-type method) are applied to the system of differential-algebraic equations resulting from the space discretisation by means of finite elements. This has the essential advantages that time-adaptivity is applicable. Moreover, there are neither global nor local iteration procedures. The lecture shows the behaviour of the new global finite element approach and compares it to classical implicit (iterative) procedures. [1] Hartmann, S.: A thermomechanically consistent constitutive model for polyoxymethylene: experiments, material modeling and computation, currently published online Archive of Applied Mechanics 2006

Modelling of mechanical twinning on the microscale. **Rainer Glüge** (Universität Magdeburg, Germany) GA/CT5062/006

Since magnesium and its alloys have been rediscovered as adequate materials for lightweight-structures, there is an increased interest in an accurate modeling of the plastic material behavior. At room temperature, mechanical twinning is an important deformation mode, which influences strongly the material properties, especially the crystallographic texture and the grain morphology. There exist some material models that incorporate mechanical twinning from a macroscopic point of view in a statistical and homogenized sense, while material models that are able to predict the twin formation on the microscale are object of ongoing research, which is due to the phase-transition character of twinning. The latter type of models is predestined to be combined with the representative volume element technique. Such approach should allow a much more precise prediction of the microstructure evolution than a statistical model. In this talk, a short comparison of some micro-models is given. Then, a modeling technique that uses a nonconvex elastic potential and the special characteristics that emerge in conjunction with mechanical twinning are discussed in detail.

GA/CTS4457/06: Ferroelasticity and other topics in materials science.

On the modelling of rate-dependent ferroelastic switching. **Andreas Menzel** (Universität Siegen, Germany), Arunachalakasi Arockiarajan (IIT Madras, India), Srinivasan M Sivakumar (IIT Madras, India) GA/CT1939/006

Piezoelectric materials, which are nowadays widely used for smart materials and intelligent systems applications, possess severely nonlinear response under high loading conditions. Such effects, as monitored by representative hysteresis and butterfly curves, stem from phase-transformations of the underlying polycrystalline microstructure. So-called spontaneous polarisation as well as spontaneous strains thereby take place of the level of individual grains or rather domains.

To account for such effects within a finite-element-based modelling approach, an energy-related switching criterion is adopted, whereby, at this stage, we restrict ourselves to ferroelasticity. In this regard, domain switching is initiated as soon as the corresponding reduction in energy exceeds a particular threshold. On the one hand, microstructural characteristics are directly incorporated by adapting the underlying (local) elastic properties, while, on the other hand, also the format of the spontaneous strains reflects the geometry of the assumed tetragonal unit-cells. Rate-dependent response, however, is phenomenologically introduced my means of a Weibull probability function weighting the switching threshold.

With this framework in hand and based on a staggered iteration technique embedded into a three-dimensional finite element formulation, numerical simulations recover representative hysteresis and butterfly curves, whereby use of randomly initialised unit-cells as well as of volume averaging techniques is made.

Contact area of solid bodies: calculations compared to measured results. **Jan-Hinrich Sick** (TU Braunschweig, Germany), Georg Ostermeyer (TU Braunschweig, Germany) GA/CT2339/006

A novel attempt is made to directly measure the contact area of solid bodies by relating it to the electrical contact resistance. This method was used by F. P. Bowden and D. Tabor in the 1930s already. We confined the setup by use of low conductive thin film coatings. This way it is possible to point out the influence of contact area in contrast to incidental contaminations. By use of wear resistant coatings it is possible to measure the contact area in sliding contacts as well. We compare new measurements to predictions of contact area calculated on base of recent models like the discrete Greenwood and Williamson model proposed by M. Ciavarella, V. Delfine and G. Demelio (2006). This project is supported by the German Research Foundation.

An evolution model in contact mechanics with dry friction. **Florian Schmid** (Weierstraß-Institut Berlin, Germany) GA/CT2464/006

We present an existence result for an evolution problem in contact mechanics with dry friction. Our physical model consists of an elastic system whose shape is determined by the position of N single particles, thus leaving only 3N degrees of freedom. You may think of N particles that are linked by nonlinear elastic springs. The whole system will be driven by external forces which we assume to evolve quite slowly in time. This will allow us to neglect inertia terms in the model. Further we assume a rigid plane to be given which cannot be penetrated by any particle. As soon as a particle comes into contact with the plane friction will occur which will be modelled using Coulomb's friction law.

Mathematically this leads us to a highly nonlinear and rate-independent problem with two severe difficulties. The first arises from the frictional term which is usually written as a multivalued functional. The second difficulty is due to the change from contact to non-contact of each particle. We are going to present an energetic formulation for such a problem and a time incremental method to prove existence. The method is such that it overcomes both difficulties at once.

Description of inelastic deformation of solids accounting for shear banding. **Ryszard Pecherski** (Cracow University of Technology, Poland) GA/CT4813/006

The subject of the study are ultra fine grain (ufg) and nanocrystalline metals (nc-metals). Experimental investigations of the behaviour of such materials under quasistatic as well as dynamic loading conditions related with microscopic observations show that in many cases the dominant mechanism of plastic strain is multiscale development of shear deformation modes - called usually shear banding. The comprehensive discussion of these phenomena is given e.g. in [1]. Our objective is to propose a new description of inelastic deformation, which accounts for the observed mechanism of shear banding. The shear banding contribution function, which was introduced formerly in [2], [3] and applied in continuum plasticity accounting for shear banding in [4], [5] plays pivotal role in the proposed description. The derived constitutive equations were identified and verified with application of available experimental data. The possibilities of the application of the proposed descrip-

tion for modelling of plastic flow of hard deformable and high strength materials are discussed.

Comparison of two integration algorithms for finite plasticity combined with nonlinear kinematic and isotropic hardening at the example of springback. **Michael Pietryga** (TU Braunschweig, Germany), Stefanie Reese (TU Braunschweig, Germany) GA/CT2258/006

In this research a large-deformation elastic-visco-plastic model with non-linear kinematic and non-linear isotropic hardening is implemented. The model is capable of describing cyclic hardening and the Bauschinger effect, which are very important for the modelling of springback in sheet metal forming. The model is derived from a thermomechanical framework and is based on the multiplicative split of the deformation gradient. A major topic of this talk is the comparison of two implicit time integration schemes: 1) a new version of the exponential map algorithm [1] and 2) a modification to the classical backward Euler method (see for earlier concepts [2]). Both algorithms fulfill plastic incompressibility. Some aspects, such as the necessity to fulfill plastic incompressibility, several possibilities to modify the classical backward Euler method in order to fulfill plastic incompressibility, or the numerical efficiency of both algorithms, are discussed. The comparison of the methods is performed at the material point level as well as at the structural level. For this purpose, the FE analysis tool ABAQUS is used. The applicability of the presented model at the structural level is demonstrated for the case of springback prediction in sheet metal forming simulations. [1] D. Christ, S. Reese, Is it necessary to model shape memory alloys within the scope of large strains?, Proceedings of SPIE: Smart Structures and Materials, Ed.: W.D. A non-local extension of the Gurson–Tvergaard–Needleman damage model for the simulation of metallic structures. **Christian Fell** (TU Darmstadt, Germany) GA/CT2452/006

The present contribution is based on a non-local extension of the model of Gurson-Tvergaard-Needleman (GTN) for ductile damage [1]. The formulation applies a multiplicative decomposition of the deformation gradient and is valid for finite plastic deformation. In order to avoid mesh dependencies of the finite-element solution a gradient-enhanced model for regularization is applied. Here, we use the gradient of the damage variable in terms of the void fraction, cf [3]. The model is able to describe void nucleation, growth and coalescence. In the original work [2] the coalescence is modeled by a bilinear relation between void fraction and modified void fraction. Opposed to this we propose a smooth relation between these quantities, which is realized by means of a higher order polynomial. Representative numerical examples serve to verify the numerical features and to validate the modelling.

On the convergence of kinetic variational inequality to quasi-static variational inequality with applications to the elastoplasticity. **Adrien Petrov** (WIAS, Germany) GA/CT2432/006

We prove a priori bounds for the dynamic elastic–plastic systems that lead to the convergence to the quasi-static case. The discussion of convergence is preceded by the presentation of mathematical formulations, existence and uniqueness results for those dynamic and quasi-static problems.

Numerical analysis of shear-bands in solids by means of computational homogenization. **Lidija Stankovic** (Ruhr-Universität Bochum, Germany), Jörn Mosler (Ruhr-Universität Bochum, Germany) GA/CT2748/006

A novel fully three-dimensional framework for the numerical analysis of shear bands in solids undergoing large deformations is presented. The effect of micro shear bands on the macroscopic material response is computed by means of a homogenization strategy. More precisely, a strain-driven approach which complies well with displacement-driven finite element formulations is adopted. The proposed implementation is based on periodic boundary conditions for the micro-scale. Details about the implementation of the resulting constraints into a three-dimensional framework are discussed. The shear bands occurring at the micro-scale are modeled by a cohesive zone law, i.e., the tangential component of the traction vector governs the relative shear sliding displacement. This law is embedded into a Strong Discontinuity Approach (SDA). To account for realistic sliding modes, multiple shear bands are allowed to form and propagate in each finite element.

3D continuum mechanical modeling of the Portevin–Le Châtelier effect. **Gèza Bondàr** (Universität Karlsruhe (TH), Germany), Thomas Böhlke (Universität Karlsruhe, Germany), Juri Estrin (TU Clausthal, Germany) GA/CT2678/006

In many Al-, Cu-, Fe- and Ni-based alloys jerky flow associated with the Portevin–Le Châtelier (PLC) effect appears within a specific range of temperature and strain rate. This effect which reduces the ductility and the surface quality of sheet materials is caused by the interaction of free dislocations with obstacles (Estrin, 1987). A three dimensional continuum mechanical model concerning the dynamic strain ageing is presented. A comparison of the predictions of the three dimensional model with experimental results is given. Special emphasis is given to the determination of the instability region in the strain and strain-rate space (Kubin and Estrin, 1990).

Aspects of shape and parameter sensitivity analysis in the theory of porous media. **Franz-Joseph Barthold** (Universität Dortmund, Germany), Jörg Stieghan (TU Braunschweig, Germany) GA/CT3112/006

This contribution is concerned with the application of variational shape sensitivity analysis and parameter sensitivity analysis to the theory of porous media. Both areas contribute to structural optimization and inverse problems like parameter identification. The correct and efficient derivation, implementation and computation of the sensitivities, i.e. the gradient values of objectives and constraints with respect to different kind of design variables, have an significant influence on the overall performance of the nonlinear programming algorithms applied to the numerical treatment of inverse problems.

The theory of porous media is build upon the mixture of several phases and their interaction. Thus, a complex continuum mechanical description for each single phase as well as for the micture is used in this approach. This proposal formulates a general viewpoint using local coordinates which permit a rigorous split of continuum mechanical functions into parts being either geometry or deformation dependent.

The variational approach to sensitivity analysis is build upon this separation and yields some general inside into the structure of porous media. Especially, the significance of the material parameters of each single phase as well as the mixture ratio for the overall deformation behavior can be quantified. We will summarize our research of the theoretical and computational treatment by means of selected examples considering soil mechanics as well as foams.

Granular materials: parameter identification and modelling of localization problems. **Okan Avci** (Universität Stuttgart, Germany), Wolfgang Ehlers (Universität Stuttgart, Germany) GA/CT3988/006

The prediction of landsliding requires an exact knowledge of the mechanical behaviour of granular materials. This kind of materials, e. g., sand, have a very complex deformation behaviour, which depend on the stress-state and the loading history. Via homogeneous triaxial tests on dry sand specimens, the material behaviour of the grain structure can be characterized. Additionally, an appropriate elasto-plastic material law to describe the solid skeleton in the frame of *Theory of Porous Media* (TPM) is used, which is implemented in the FE tool PANDAS. Furthermore, a single-surface yield criteria with isotropic hardening, which limits the elastic domain, and non-associated plastic flow is assumed.
The determination of the material parameters of the linear elasticity law as well as the single-surface yield criteria based on test data of triaxial experiments is done with a derivative based optimization method (donlp2), which is coupled with PANDAS. Finally, a simulation of a benchmark test is presented to show shear band localization effects. In this case, the material behaviour is described by a triphasic porous media model based on the TPM, where the single constituents are a deformable solid skeleton and two pore fluids, i. e., pore water and pore air.

Adaptive modeling and simulation of shear banding and high speed. **Christian Hortig** (Universität Dortmund, Germany), Bob Svendsen (Universität Dortmund, Germany) GA/CT2137/006

High speed cutting is a process of high interest in modern production engineering. Besides the advantage of high productivity as a result of the increase of cutting speed, a decrease of cutting forces can be observed. In order to take advantage of the potential of the high speed cutting process, the knowledge of the working mechanisms in combination with the material behavior is essential. Experimental observations detect the occurrence of localized adiabatic shear bands as the main mechanism of deformation of chip formation. These shear bands develop in localized areas of temperature dependent softening, surrounded by material in a process of strain and strain rate dependent hardening. The fact of high deformation rates and the mechanism of localized shear bands forces the implementation of a temperature and rate dependent material model which will be discussed. The strong mesh dependence of the phenomenon of localized shear banding is one of the key problems in the context of FE simulation of the high speed cutting process, as orientation and characteristic length of the mesh force direction respectively expansion of localization. It will be shown that the influence of the orientation of the mesh can be reduced by using adaptive procedures with the aim to reduce the characteristic element length locally. Here, a Python environment is used to connect the different components of the adaptive procedure, consisting of the error estimator, the mesh generator, the mapping procedure and the solver. The adaptive procedure will be discussed in detail. Besides a reduced mesh dependence, using adaptive remeshing enables a more realistic modeling of the separation of the chip and the resulting surface. Up to this point the presented simulation results are restricted to the 2D case. The pathological mesh dependence and thus the characteristic element edge length forces the width of the material instability. Thus an additional information is required to give a physical description of the width of the material instability. Here the formulation of a non local plasticity model is favored and implemented. Simulation results will be presented.

Boundary-value problems in the theory of binary mixtures. **Merab Svanadze** (Ilia Chavchavadze State University, Georgia) GA/CT615/006

Great strides have been made in developing a theoretical basis for studying the mechanics of mixtures starting with the pioneering work of Truesdell and Toupin (1960). The mathematical models of the binary mixtures of elastic and thermoelastic solids are presented by Green and Naghdi (1965), Steel (1967), Lempriere (1969), Bedford and Stern (1970), Filippov (1971), Rushchitski (1978), McNiven and Mengi (1979), Khoroshun and Soltanov (1984), and Iesan (1997).

In this paper a wide class of the boundary value problems of the linear theory of binary mixtures of elastic and thermoelastic solids is investigated by means of the boundary integral method (BIM). The fundamental solutions of the equations of steady oscillations for mathematical models of the binary mixtures are constructed in terms of elementary functions.

The uniqueness and existence theorems of solutions of the interior and exterior boundary value problems by means BIM

and multidimensional singular integral equations are proved. The Sommerfeld-Kupradze type radiation conditions are established.

The existence of eigenfrequencies of the interior homogeneous boundary value problems of steady oscillations is studied. The basic properties of wave numbers are treaded. The connection between plane waves and eigenfrequencies is established. The formula of asymptotic distribution of eigenfrequencies is obtained.

Boundary-value problems of the theory of heat propagation in a binary mixture. **Maia Svanadze** (Tbilisi State University, Georgia) GA/CT844/006

The linear mathematical models of heat propagation in a binary mixture are presented by Gurtin and De La Penha (1970), Khoroshun and Soltanov (1984), Iesan (1997).

In this paper the boundary value problems of steady oscillations of the linear theory of heat propagation in a binary mixture are investigated. The fundamental solution of the system of the equations of steady oscillations is constructed in terms of elementary functions. A solution of Galerkin type is established. The integral representation of Somigliana type for the regular vectors is presented. The basic properties of single-layer, double-layer and volume potentials are studied. The uniqueness and existence theorems of solutions of the interior and exterior boundary value problems by means boundary integral method (potential method) are proved.

On the construction of anisotropic polyconvex energy densities. **Vera Ebbing** (Universität Duisburg-Essen, Germany), Jörg Schröder (Universität Duisburg-Essen, Germany), Patrizio Neff (TU Darmstadt, Germany) GA/CT2365/006

In order to guarantee the existence of solutions in large strain elasticity, the free-energy function has to be quasiconvex. This condition is rather complicated to handle. Therefore, polyconvex functions which are always quasiconvex are usually considered, see [1]. For isotropic materials, there exists a wide range of constitutive functions that satisfies the polyconvexity requirement. In this talk we discuss the formulation of anisotropic polyconvex free energy functions in a coordinate-variant setting. A variety of polyconvex energy densities in a transversely isotropic and orthotropic coordinate-invariant framework has been proposed in [2,3]. The goal of the talk is the construction of constitutive functions in terms of the elements of a local functional basis which automatically satisfy the polyconvexity condition. The local functional basis is considered in a preferred frame and consists of terms of the right Cauchy-Green tensor. After giving a general introduction we focus on several model problems and present some numerical examples.

Polyconvex energy densities with applications to anisotropic thin shells. **Daniel Balzani** (Universität Duisburg-Essen, Germany), Jörg Schröder (Universität Duisburg-Essen, Germany), Friedrich Gruttmann (TU Darmstadt, Germany) GA/CT1872/004

The numerical framework for the simulation of anisotropic thin shells is presented by using polyconvex strain energy functions. The nonlinear shell theory is based on the Reissner-Mindlin kinematic along with inextensible director vectors and enhanced assumed shell strains are considered, cf. [1]. For the variational framework we consider a three field variational functional taking into account independent displacements, enhanced strains and stress resultants, where the latter field is eliminated applying some orthogonality conditions. The iterative fulfillment of the zero normal stress condition at the integration points allows consideration of arbitrary three-dimensional constitutive equations. Thus the developed four-node shell element with 5 or 6 nodal degrees of freedom can account for finite deformations. For the representation of the anisotropy we use the concept of structural tensors and formulate the strain energy function in terms of the principal and mixed invariants of the right Cauchy-Green tensor and the structural tensor. Due to the fact that we are interested in fiber-reinforced materials we consider an additive structure of the energy decoupled into an isotropic part for the matrix and a superposition of transversely isotropic parts for the fiber families. In order to guarantee the existence of minimizers *a priori* and additionally satisfy the quasiconvexity- and Legendre-Hadamard condition, we focus on polyconvex strain energy functions as proposed in [2], see also [3]. Numerous numerical examples show the anisotropy effect by comparing isotropic shells with anisotropic ones.

Stability of elastic composite materials having a negative-stiffness phase. **Dennis Kochmann** (Ruhr-Universität Bochum, Germany), Walter Drugan (University of Wisconsin, USA) GA/CT1911/006

Composite materials theory limits the attainable overall elastic moduli of a composite in terms of the properties of its constituents, presuming positive-definiteness (positive stiffness) for each constituent to ensure overall stability. Admittance of a negative-stiffness phase, however, facilitates the composite material to strongly exceed these well-known bounds. Recent experimental results give evidence for this behavior and exhibit bound-exceeding performance. However, no analytical investigation has been reported to prove overall stability for such a composite material.

An analytical method is established to derive the admissible ranges, for dynamic overall stability, for the elastic moduli of homogenous, isotropic linear-elastic bodies with arbitrary geometry and boundary conditions. This method is confirmed for two-dimensional circular geometries by proving the requirements of positive-definiteness (for a body with pure traction

boundary conditions) and strong ellipticity (for pure displacement boundary conditions). This approach at hand, it is feasible to derive stability bounds on the elastic moduli for any set of geometry and boundary conditions.

A two-dimensional (plane strain) model of a two-phase composite material is employed to obtain restrictions on the elastic moduli of a composite consisting of a coated circular-cylindrical inclusion. Our general results are simplest to interpret in the case of a thin coating. In this case, our results show that the inclusion may indeed violate positive-definiteness (within the range of strong ellipticity), given a coating with sufficiently stiff elastic moduli (satisfying a restriction stronger than positive-definiteness), while retaining overall stability of the composite. Therefore, a negative stiffness inclusion can be stabilized by a sufficiently stiff coating. This approach may give rise to novel advances into composite materials with superior performance.

Modeling dissipative effects in anisotropic materials by means of evolving generalized structural tensors. **Alexander Ehret** (RWTH Aachen, Germany), Mikhail Itskov (RWTH Aachen, Germany) GA/CT2943/006

Structural tensors are a practical means to describe anisotropic properties of a material. They allow to define the symmetry group of the material and finally to incorporate anisotropic behavior into constitutive models. Recently, polyconvex anisotropic hyperelastic models were proposed which are based on linear combinations of the structural tensors referred to as generalized structural tensors. The corresponding non-negative components represent weight factors of the preferred material directions and are considered as material constants of the constitutive model. In the present contribution, these weight factors and consequently the generalized structural tensors are allowed to change in order to describe evolving material properties. This approach enables to account for dissipative effects in anisotropic materials like e.g. softening or the so-called preconditioning, which is experimentally observed in biological soft tissue samples during early load cycles. Applying the theory of internal variables, the relevant thermodynamic quantities are derived, suitable yield conditions are discussed and appropriate evolution equations are suggested. As a numerical example, the preconditioning behavior of soft tissue samples is considered.

Cyclic martensitic phase transformation of monocrystals with finite strains. **Gautam Sagar** (Universität Hannover, Germany), Erwin Stein (Universität Hannover, Germany) GA/CT2312/006

Based on BainŠs principle, a C^1-continuous thermo-mechanical micro-macro constitutive model for monocrystals with finite strains and hyperelastic free energy function is used. It is represented by a unified non-convex Lagrangian variational functional including phase evolution equations with mass conservation and quasi-convexification during phase transformation processes. The convexification problem is solved here by generalizing the explicit form of the lower Reuss bound for small strains given by Govindjee, Mielke and Hall (2003) to finite strains. Iterative time integration of the evolution equation is programmed in C++ and implemented into the UMAT-interface of the finite element package Abaqus for the current configuration associated with Jaumann rate. The validation of this phase transformation model is carried out for both quasiplastic and superelastic effects of $Cu_{82}Al_{14}Ni_4$ monocrystals with experimental data supplied by Xiangyang et al. (2000). Computations are done using 3D-hexahedral B-bar elements. The numerical results give good agreement with experimental values. An interesting result of numerical simulation is the local average behavior of *yield tooth* pattern (measured zig-zag curves) which could not be represented by linear theory.

On the implicit standard material model. **Michael Ban** (RWTH Aachen, Germany), Dieter Weichert (RWTH Aachen, Germany) GA/CT2335/006

The Implicit Standard Material (ISM) model, introduced by de Saxcé, is an extension of the Generalized Standard Material model. The ISM model allows to analyze coupled and non-associated constitutive laws of potential type. The mathematical framework is based on separately convex functionals, called bipotentials. In our presentation, we focus on variational methods for the ISM model and applications to shakedown theory.

Comparative analysis of viscoelastic models involving fractional derivatives of different orders. **Marina Shitikova** (Voronezh State University, Russian Federation), Yuriy Rossikhin (Voronezh State University, Russian Federation) GA/CT863/006

In the given paper, a comparative analysis of the models involving fractional derivatives of different orders is given. Such models of viscoelastic materials are widely used in various problems of mechanics and rheology.

In particular, it is shown the equivalence of the model presented by Koeller (1984)

$$\sum_{i=1}^{n} a_i D^{i\alpha}\varepsilon = \sum_{j=1}^{n} b_j D^{j\alpha}\sigma, \qquad (1)$$

and the model proposed by Rabotnov (1966)

$$\varepsilon = J_\infty \left[\sigma + \sum_{i=1}^{n} g^i \ni_\alpha^* (-\tau_i^{-\alpha})\sigma\right], \qquad (2)$$

where $D^{i\alpha}\varepsilon$ and $D^{j\alpha}\sigma$ are Riemann-Liouville fractional derivatives of the strain and stress, respectively, a_i, b_j, g_i, and τ_i are given values, $0 < \alpha < 1$ is the order of the fractional derivative, J_∞ is the instantaneous compliance, the operator

$$\ni_\alpha^* (-\tau_i^{-\alpha})\sigma = \int_0^t \ni_\alpha (-t'/\tau_i)\sigma(t-t')dt',$$

and the fractional exponential function

$$\ni_\alpha (-1, t'/\tau_i) = \frac{t^{\alpha-1}}{\tau_i^\alpha} \sum_{n=0}^{\infty} (-1)^n \frac{(t/\tau_i)^{\alpha n}}{\Gamma[\alpha(n+1)]}$$

goes over into an ordinary $\exp(-t/\tau_i)$ at $\alpha = 1$ ($\Gamma[\alpha(n+1)]$ is the gamma-function).

Inverse of the Rabotnov's model (2) is carried out, and it is shown how to apply it for approximation of hereditary kernels determined experimentally.

Representation of the linear viscoelastic behaviour of wood with a constitutive theory based on fractional time derivatives. **Thomas Ranz** (Universität der Bundeswehr München, Germany) GA/CT3620/006

Like many other materials used in mechanical and civil engineering, wood shows a pronounced history-dependent mechanical material behaviour. Due to its anisotropy its rheological behaviour is strongly dependent on the direction. In this research project, the material behaviour is represented with a phenomenological theory of anisotropic fractional viscoelasticity. In order to identify the material functions and parameters, the time-dependent creep compliances are measured in three orthogonal directions under tension and shear. As a result of the developed constitutive approach, the experimentally observed creep data is described by several power functions. In the second part of the presentation, some differences between classical models of viscoelasticity which are based on Kelvin-Voigt or Maxwell elements and the fractional approach are presented. The assets and drawbacks with respect to wood are discussed.

Critical remarks on finite multiplicative visco-elasticity and formulation of finite fractional visco-elasticity. **Alexander Lion** (Universität der Bundeswehr, Germany) GA/CT1307/006

A critical consideration of the theory of finite multiplicative viscoelasticity splitting the deformation gradient into a set of elastic and inelastic parts in parallel and introducing corresponding intermediate configurations is given. If different intermediate configurations are taken in parallel, this approach leads to a set of nonlinear evolution equations for the inelastic deformation tensors and corresponds to a generalization of discrete relaxation spectra to finite strains. Since there is no internal variable-free formulation of this approach its generalization to continuous spectra or to a fractional derivative-based theory of finite viscoelasticity is not possible. To this end, a different formulation of finite viscoelasticity is discussed: it is formulated without any split of the deformation gradient, includes discrete as well as continuous relaxation spectra and can easily be used to formulate a fractional derivative-based theory of finite viscoelasticity. The most simple model of this type corresponds to the well-known springpot of one-dimensional fractional viscoelasticity and interpolates between the Mooney Rivlin model of finite elasticity and the model of the linear viscous fluid. This model leads to a relaxation behaviour of the power-law type, but more complicated models of this type lead to a relaxation behaviour which is given by Mittag–Leffler functions.

3D finite-element modeling of polymeric materials with C^1-continuous elements. **Paul Fischer** (TU Kaiserslautern, Germany), Ellen Kuhl (TU Kaiserlautern, Germany), Paul Steinmann (TU Kaiserslautern, Germany) GA/CT2262/006

Motivated by recent development in compound polymeric materials, we aim to model microfibrillar polymer-polymer composites. This can be accomplished in two different ways, macroscopic phenomenologically or microscopically-motivated. Here, we followed the latter approach. To this end, entropy elastic chain models like the Langevin model are embedded in various kinds of representative unit cells. This provides a constitutive model for the material. The finite element method with the classical Jacobian-pressure formulation is most common to avoid locking and other numerical instabilities. In the recent literature an alternative strategy based on a single field 3D Hermitian element with C1 interelement continuity of the displacements has been suggested. The fundamental advantage of these elements is a continuous stress interpolation. Numerical examples will demonstrate their improved convergence properies as compared to classical mixed finite elements.

Measurement of the elastoplastic strain at the crack tip on the specimen. **Yuri Lapusta** (Institut Français de Méchanique Avancée, France), Petro Yasniy (Ternopil State Ivan Pulu'j Technical University, Ukraine), Yuriy Pyndus (Ternopil Ivan Pul'uj State Technical University, Ukraine), Ihor Shulgan (Ternopil State Technical University, Ukraine) GA/CT4132/006

An experimental technique for study of the elastoplastic strain at the crack tip is proposed. It deals with the determination of the elastoplastic displacements of the material on the plane center cracked panel surface and the identification of the elastoplastic deformations at the crack tip using an improved method of coordinate grids. The technique uses chemical etching of a grid (100 dots per mm2) with constant step gradation on the specimen surface. The point diameter approximately equals 0.02 mm. Phototype-setting device Scitex-Dolev4pressVEG750 (resolution 4064 dots per inch) is used to prepare the grid phototemplate (negative). The depth of grid holes is 2-3 micrometers. Such grid has a good resistance to high strains including high temperature. It has high accuracy, contrast and constant step. The digital images of specimen surface at the crack tip before loading and at the maximum tensile load and after unloading were obtained. To photograph the coordinate grid, a binocular microscope (magnification factor - 70x), a digital camera Sony (Carl Zeis optics) with resolution (6 Megapixels) and some illuminating equipment were used. A program for the calculation of coordinate grid points displacement was developed. This program is based on a bit-by-bit coordinate grid points digitalization, an automated determination and identification of the grid points center coordinates on the virgin and deformed material pictures, and on calculation of their displacement and strain. Stress-strain state at the crack tip under similar loading conditions was carried out using FEM. The plane stress state was considered. The calculations were carried out for a uniaxial loading of center cracked panel of aluminium alloy D16chT (analogue of American 2024T3). A comparison of the elastoplastic and plastic strains at the crack tip calculated using the FEM and using the grids method was performed.

Ferroelektriosche Piezokeramiken: Experimente, Mikromechanik, Materialmodelle und Finite Elemente Analyse. **Marc Kamlah** (Forschungszentrum Karlsruhe, Germany) GA/CT3607/006

Dies ist ein von Prof. A. Lion eingeladener Beitrag in der Sektion Materialtheorie.

Koautoren: B. Laskewitz und D. Zhou

Abstract: Die wichtigste Materialklasse fuer die Ausnutzung des piezoelektrischen Effektes, der zunehmende Bedeutung in Aktorik und Sensorik besitzt, sind ferroelektrische Keramiken. In diesem Vortrag stellen wir zunaechst die mikroskopische Struktur des Materials mit Domaenen und Umklappprozessen vor. Sodann diskutieren wir ein mikromechanisches Volemenelement. Weiterhin werden ein phaenomenlogisches und ein mikroskopisch motiviertes Materielmodell vorgestellt. Schliesslich betrachten wir die Anwendung dieser Modelle in der Finiten Elemente Analyse von Polungsprozessen in piezokeramischen Komponenten.

Simulation of asymmetric effects for shape-memory alloys. **Stefan Wilmanns** (Universität Paderborn, Germany), Rolf Mahnken (Universität Paderborn, Germany) GA/CT1683/006

Extended experimental tests for shape memory alloys exhibit different behaviours for different loading types, such as tension, compression and shear. These observations, labelled here briefly as asymmetric effects, are reported in the literature; e.g., in [1] or [2]. The paper is concerned with modelling of these effects in the framework of plasticity. To this end an additive decomposition of the flow rule is assumed into a sum of weighted stress mode related quantities. The characterization of the stress modes is obtained in the octahedral plane of the deviatoric stress space in terms of a single scalar variable, such that stress mode dependent scalar weighting functions can be constructed. Furthermore the numerical implementation into a finite element program of the resulting set of constitutive equations is outlined. For parameter identification a sequential strategy exploiting the mode decomposition and the individual loading scenarios, such as tension, compression and shear, respectively is described. Verification of the proposed methodology is succeeded for simulation of the pseudoelastic behaviour of shape memory alloys with different hardening characteristics in tension and shear.

Thermo-mechanical behavior of pseudo-elastic NiTi *shape-memory alloys.* **Patrick Luig** (Ruhr-Universität Bochum, Germany), Christian Grabe (Ruhr-Universität Bochum, Germany), Otto Bruhns (Ruhr-Universität Bochum, Germany) GA/CT2376/006

The thermomechanical behavior of polycrystalline Ni-rich pseudoelastic NiTi shape memory alloys is analyzed. Special focus is on regions within the stress strain diagram which are regarded as linear elastic in common phenomenological material models, i.e. the region between zero stress and the beginning of the pseudoelastic plateau as well as the region within the hysteresis. In both cases, severe temperature changes can be observed. A possible explanation for this effect is twofold: On the one hand, it might be explained by the presence of an R-phase transformation. On the other hand, self-accommodated martensite of the B19' phase may form. However, the assumption of a purly linear elastic material behavior in those regions does not seem to hold true in general.

A new method for the simulation of shape-memory polymers. **Markus Böl** (TU Braunschweig, Germany), Stefanie Reese (TU Braunschweig, Germany) GA/CT1971/006

Shape memory polymers belong to the group of smart materials that can be easily formed into complex shapes, retaining memory of their original shape even after undergoing large deformations. This characteristic makes the material interesting for medical application fields. Here it is used as stent or suture material, where the memory effect is controlled by the temperature of the body. The shape memory properties can be quantified by cyclic thermomechanical investigations. One cycle includes the "programming" of the specimen and the recovery of its permanent shape. In a typical test program the specimen is stretched up at room temperature to a certain stretch λ_{m}. The sample is then cooled at constant stretch λ_{m}. If the transition temperature is reached the shape of the sample is fixed. After reheating to the transition temperature the sample is contracting itself and the original shape is restored. For the simulation of such material behaviour under varying thermal and mechanical conditions while the polymer undergoes large deformations we present an innovative finite element model which incorporates the micro structure of rubber-like material.The proposed approach is based on a so-called unit cell consisting of one tetrahedral element and six truss elements. On each edge of the tetrahedron one truss element is attached which models the force-stretch behaviour of a bundle of polymer chains. Connecting this elastic behaviour of rubber-like material with the thermal one, the proposed method provides the possibility to observe how changes at the microscopic level influence the macroscopic material behaviour also under varying thermal conditions.The main focus of this work is the influence of both, the material constants and heat transfer boundary conditions on the response of shape memory polymers. To conclude we illustrate different examples of application.

Numerical simulation of the material behavior of pre-textured poly-crystalline shape-memory alloys. **Rainer Fechte-Heinen** (Ruhr-Universität Bochum, Germany), Klaus Hackl (Ruhr-Universität Bochum, Germany) GA/CT1959/006

We present a micromechanical model for polycrystalline shape-memory alloys. The main focus of our model is the orientation distribution of the austenitic and martensitic variants. We assume the material to consist of a large but finite number of randomly oriented crystallites in which the material is able to transform inbetween the high- and low-temperature-phase. The material behavior then originates from the accommodation of the orientation distribution of all variants in order to minimize the free energy density. By this ansatz, the internal reorientation of martensite can be predicted. Hysteresis effects are included via the hypothesis that changes in the orientation distribution are connected with energy dissipation by a function of first order. The model is capable of reproducing all essential effects in the material behavior of shape memory alloys such as pseudoelasticity and pseudoplasticity as well as the influence of pre-texture caused by the production process.

Experimental as well as numerical validation based on the works of Smyshlyaev & Willis are shown.

Zu den Auswirkungen von Selbstorganisationsprozessen auf das makroskopische mechanische Verhalten hochmolekularer Werkstoffe. **Jörn Ihlemann** (Deutsches Institut für Kautschuktechnologie, Germany) GA/CT3008/006

Die hochmolekularen Werkstoffe unterteilen sich gemäß ihrer mechanischen Eigenschaften grob in Duromere, Thermoplaste und Elastomere. Die Duromere sind räumlich eng vernetzt, zeigen ein weitgehend elastisches Verhalten und eine vergleichsweise geringe Verformbarkeit. Hingegen ist das mechanische Verhalten der Thermoplaste bei größeren Verformungen durch das plastische Abgleiten der nicht vernetzten Makromoleküle charakterisiert. Die technischen Elastomere zeigen eine Kombination großer, weitgehend reversibler Deformationen mit ausgeprägten, inelastischen Effekten und belastungsinduzierten Änderungen des stark nichtlinearen Materialverhaltens. Nach wie vor werden Ansätze zur physikalischen Erklärung dieser Eigenschaftskombination anhand des molekularen Aufbaus bezüglich ihrer Widerspruchsfreiheit zu physikalisch-chemischen und phänomenologischen Befunden diskutiert.

Ein großes Erklärungspotential zeigt die Theorie sich selbst organisierender Bindungsmuster (SOLP = Self-Organizing Linkage Patterns). Diese Theorie basiert auf der Annahme, daß sich während eines Belastungsvorgangs die Verteilungen der zwischenmolekularen, physikalischen Bindungen und ihrer jeweiligen Belastungen infolge massiver Auf- und Abbauraten zu einem im Verhältnis zu den ursprünglichen Unregelmäßigkeiten der molekularen Struktur großräumigen Muster prozeßspezifischer Inhomogenitäten aus verstärkten und entfestigten Bereichen organisieren. Der sich mit dem Muster entwickelnden Verschaltungscharakteristik der Bindungen innerhalb des molekularen Netzwerks wird eine wesentliche Bedeutung bezüglich des momentanen makroskopischen mechanischen Verhaltens unterstellt.

Zur Uberprüfung der Theorie und zur näheren Erforschung dieser Vorgänge dient ein Sondierungsprogramm, dessen Resultate die Existenz der Selbstorganisationsprozesse und deren unmittelbaren Zusammenhang mit dem mechanischen Verhalten der Gummimaterialien bestätigen. Durch aufwendige Abstraktionsmaßnahmen und speziell angepaßte numerische Algorithmen gelingen mit diesem Sondierungsprogramm im Rahmen moderater Computerkapazitäten Simulationen relevanter Prozesse, wobei wesentliche Effekte des mechanischen Verhaltens von Gummi reproduziert werden.

Experimental investigations on the mechanical behavior of filled rubber. **Michael Dämgen** (Medizinische Hochschule Hannover, Germany), Udo Nackenhorst (Leibniz Universität Hannover, Germany) GA/CT2108/006

The mechanical properties of technical rubber are roughly described by the non-linear elastic behavior but incompressible behavior with extremely high fracture tension, hysteretic behavior under cyclic conditions, stiffening under dynamic loading and damage due to overloading. This behavior is explained from the microstructure of elastomers and influenced by the basic polymer system, the treatment for networking and filler reinforcement. An amount of models exist to explain this behavior, but a suitable data-basis for model validation is missing. Therefore, in this contribution experimental studies on the mechanical behavior of well defined rubber systems will be presented. By uniaxial tension and compression tests the rubber-mixtures are compared regarding their stress softening (Mullins effect), remaining plastic strain, hysteresis, etc. These results will also be compared with those obtained from shear-tests. Additional measurements have been performed with respect to the characterization of damage induced anisotropy, relaxation behavior and temperature dependency of both, initial mechanical properties and annealing behavior. Besides a critical review of different measurement techniques on the reliability, the capability of state of the art models implemented in commercial finite element programs will be discussed.

Amplitude-dependent phenomena of filler-reinforced rubber: experiments, modelling and simulation. **Philipp Höfer** (Universität der Bundeswehr München, Germany) GA/CT2648/006

It's a matter of common knowledge, that carbon black- or silica-loaded elastomers show a pronounced nonlinearity when excited with dynamic deformation amplitudes, namely the Payne-effect. While intact at low amplitudes, the filler network is destroyed with increasing strains leading to a decrease in the storage modulus and to a distinct maximum in the loss modulus at intermediate amplitudes. Furthermore, several experiments prove a very complex history-dependence; for example, a significant recovery-behaviour after an amplitude jump or the observed hole-burning effect.

In the present talk, a few experimental results of dynamical measurements on filler-loaded rubber are shown with importance attached to the complicated history dependence. In order to describe the depicted phenomena, a thermodynamic consistent model of nonlinear viscoelasticity is presented. The model is based on intrinsic time scales which are driven among others by the current state of the filler network. In contrast to models in the frequency domain, the present formulation can be easily implemented into Finite-Elements and solved for arbitrary loading processes. Corresponding numerical results of the presented model are shown and compared with given experimental results.

On phenomenological and micro-mechanical models in finite elasticity and viscoelasticity for rubber-like materials. **Mokarram Hossain** (TU Kaiserslautern, Germany), Paul Steinmann (TU Kaiserslautern, Germany), Ralf Denzer (TU Kaiserlsautern, Germany) GA/CT2204/006

Nowadays, polymeric materials have many commercial and engineering applications. Some polymers not only show elastic behaviour but also complex time-dependent behaviour when subjected to a history of stress or strain. There are several phenomenological based models and micro-mechanically motivated network models for elastic and viscoelastic polymeric materials which have been proposed in the literature. The 8-chain, 3-chain models (elastic), full network models (elastic), micro-macro unit sphere (21-chain) models are well-known models which can be used for moderate to large elastic and viscoelastic deformations of polymeric materials. The Ogden model is one of the classical phenomenological models for elastic and viscoelastic polymeric materials.

The aim of the research work is to compare various phenomenological and micro-mechanical models for elastic and viscoelastic processes at large deformation.

Representation of static and dynamic elastomer behaviour and industrial applications. **Herbert Baaser** (Freudenberg AG, Germany) GA/CT1246/006

The aim of the talk is the description of a phenomenological material model incorporating the static and dynamic behaviour of elastomers for industrial applications such as seals and dampers. These highly nonlinear effects are connected with the names of MULLINS and PAYNE, respectively.

In that sense, we identify stress softening (MULLINS) and permanent deformation as inelasticity, and describe additionally the occurence of viscoelasticity (PAYNE) in parallel, which is typically known for elastomers to decrease the dynamic stiffness with increasing the strain amplitude.

These individual effects are covered separately in the constitutive law. This permits a largely modular design of the material description on the basis of user interfaces in commercial FE programs and a much easier parameter adjustment. On the as-

sumption of a multiplicative decomposition of the deformation gradient into a hyperelastic and an inelastic part, the modeling of metal materials within the scope of finite deformations has been established itself a considerable time ago. This concept is now adequately transferred to the considered material class and expanded accordingly.

In addition, the hyperelastic part of the material answer is defined on the basis of any freely chosen function of the strain energy (density), while the modeling of the inelastic parts is based on the formulation of a non-linear, isotropic hardening. The aforementioned description of stress softening in the hyperelastic part is additionally controlled by means of the first invariant of the elastic deformation. The branch of time domain viscoelasticity is realized by the use of a hereditary integral formulation and the help of PRONY series, where a well-defined parameter calibration is focused especially in that part of the presentation.

Simulating solid-state sintering and compaction of metal powder in the finite-strain regime. **Jan Frischkorn** (TU Braunschweig, Germany), Stefanie Reese (TU Braunschweig, Germany) GA/CT2281/006

Large ring-shaped workpieces manufactured by radial-axial ring rolling which are powder-metallurgically covered with wear resistant outer layers using the HIP-technology can be found in many industrial applications (e.g. mills for crushing mineral goods, bearing rings). The HIP-process limits the maximum possible ring diameter and is very expensive, too. A remedy to this problem is expected from integrating the sintering and compaction of the metal powder into the ring rolling process. For this purpose, a material model has been developed which is able to describe solid state sintering as well as compaction under high temperature where sintering effects are still active. The continuum mechanically-based model (derived on the basis of [1]) is formulated in the large strain regime to cover geometrical nonlinearities. Visco-plastic behaviour is described in form of an overstress function of the Perzyna type. Assuming an associative flow rule, the evolution equations of the internal variables can be derived from a pressure sensitive convex yield function. Furthermore, exploiting the Clausius-Duhem inequality guarantees thermodynamic consistency of the model. The use of an exponential mapping integration scheme ensures that the plastic compression described by the model is realistically simulated.

Modeling and computation of metal powder compaction processes. **Stefan Hartmann** (Universität Kassel, Germany) GA/CT2256/006

Compaction processes of metal powder indicate the application of a finite strain plasticity model for very large volumetric compression behaviour to represent the experimental observations. In this lecture a new constitutive model based on a convex and unique single surface model using a logarithmic interpolation concept of two simpler yield functions is adapted to experimental data of die compaction experiments. The yield function is controlled by internal variables so that the convexity condition of the yield function and the thermo-mechanical consistency in the sense of the Clausius-Duhem inequality is satisfied during all possible compaction processes. The constitutive model is based on the multiplicative decomposition of the deformation gradient into an elastic and a plastic part, a hyperelasticity relation of Simo&Pister type using stress and strain measures relative to the plastic intermediate configuration and an associative flow-rule. This constitutive model is implemented into a time-adaptive finite element program using high-order diagonally implicit Runge-Kutta methods in combination with the Multilevel-Newton algorithm which are applied onto the DAE-system resulting from the vertical line method in the context of finite elements. This concept preserves the structure of currently applied implicit finite element programs. A known order reduction phenomenon and the influence of a Perzyna-type regularization will be studied. In this respect it becomes apparent that a Newton-Raphson method on Gauss-point level for computing the internal variables will fail in most situations. Accordingly, other solution procedures must be investigated. Here, a constrained line-search and an arc-length approach are studied showing that the line-search approach shows the most efficient choice.

Modeling and simulation of extrusion of aluminum alloys. **Tobias Kayser** (Universität Dortmund, Germany), Christian Hortig (Universität Dortmund, Germany), Farhad Parvizian (Universität Dortmund, Germany), Bob Svendsen (Universität Dortmund, Germany) GA/CT2287/006

The purpose of this work is the modeling and simulation of the material behavior of alumminum alloys during extrusion processes. In particular, attention is here focused on Al-Mg-Si alloys of the 6000 series, which are characterized by providing a maximum of ductility and Al-Zn-Mg alloys of the 7000 series, which show better hardness properties but reduced ductility. During extrusion the material behavior is governed by the process of dynamic recovery, whereas static re-crystallization is the dominating process during cooling. In both cases the current material model is based on the role of energy stored in the material during deformation as the driving force for microstructural development. Information about the developing microstructure (e.g., texture, dislocation structures, etc.) and the influence of process conditions such as extrusion rate and temperance affect on it are provided by experimental results. State quantities like dislocation density, average grain size and grain orientation are described by using the concept of internal variables. Constitutive equations for these quantities are formulated in a thermodynamically-consistent fashion as part of a thermo-elastic, visco-plastic model with heat conduction. Applications to the case of extrusion with cooling will be presented.

Flow of viscoplastic material through converging channels. **Sergey Aleksandrov** (Institute for Problems in Mechanics RAS, Russian Federation), Elena Lyamina (Institute for Problems in Mechanics RAS, Russian Federation), Gennady Mishuris (Rzeszow University of Technology, Poland) GA/CT443/006

Flow through converging channels is one of the classical problems in plasticity theory. The first solutions of this kind for both wedge-shaped and axisymmetric channels have been obtained for rigid perfectly/plastic material. Though subsequent generalizations of these solutions on other material models have been proposed, it is easy to verify by inspection that most of these generalizations fail in the case of the maximum friction law (this law postulates that the friction stress is equal to the local shear yield stress). This results from the fact that the qualitative asymptotic behaviour of solutions in the vicinity of maximum friction surfaces strongly depends on the constitutive law chosen. In particular, in the case of viscoplasticity none of available generalizations reduces to the classical solutions, though the viscoplastic model reduces to the model of classical rigid plasticity at certain set of parameters. It is therefore of interest to propose such a viscoplastic law that leads to a solution which does reduce to the classical one. In this way it is possible to construct a unified theory of plasticity which would cover a wide range of temperatures and strain rates with a continuous (in certain sense) transition of solutions from low temperatures and strain rates to high temperatures and strain rates. In the present paper a viscoplastic model with a saturation stress is adopted to find the solution for flow through wedge-shaped and axisymmetric channels. It is shown that the asymptotic behaviour of the solution in the vicinity of the maximum friction surface depends on the parameters of the model but there is a set of parameters at which the viscoplastic solution shows the same features as the classical solution.

The multiple intermediate configuration approach and its influence on DIRK/MLNA finite-element procedures. **Karsten Quint** (Universität Kassel, Germany), Stefan Hartmann (Universität Kassel, Germany) GA/CT2340/006

According to the proposals of Lion [1] and Tsakmakis/Willuweit [2] kinematic hardening can be modelled using an additional multiplicative decomposition of the plastic part of the deformation gradient in the multiplicative decomposition approach. In this context, two flow rules control the evolution of the intermediate configurations, which are formulated on the basis of the von Mises yield function in the Mandel stress space.

Both flow rules describe the *plastic incompressibility*. The application of Runge–Kutta like integration procedures can not guarantee the incompressibility condition. Accordingly, projection methods in the sense of geometry preserving method have to be applied.

In this lecture, stiffly accurate diagonally implicit Runge–Kutta methods (DIRK) in combination with the Multilevel-Newton algorithm (MLNA) are extended by a projection step so that plastic incompressibility is satisfied. Numerical studies are performed to investigate the achievable order of high-order integration methods, the time-adaptive behaviour and the influence of the geometry-preserving algorithm to the stability, accuracy and efficiency of the method under consideration.

On the influence of phase-transformations on the experimental determination of micromechanical model-parameters. **Thorsten Bartel** (Ruhr-Universität Bochum, Germany), Klaus Hackl (Ruhr-Universität Bochum, Germany) GA/CT2508/006

In the context of a micromechanical model for materials undergoing multivariant solid–solid phase transformations, which has been developed by the authors, the question arises in which way certain quantities can be determined sufficiently. At a first glance, the question may appear trivial because it's a well established strategy to fit model-parameters like those governing the width and the height of hysteresis loops by comparing numerical results to experimental data. Yet, we entertain some doubts concerning this matter and would like to discuss whether tests on specimens are able to provide significant results in the aforementioned context at all.

To verify this, we discretize a specimen by finite elements and simulate tension tests taking different boundary conditions into account. We compare the respective results to each other and to the outcome of a material-point computation performed with our micromechanical model, respectively.

Thermo-mechanics of martensitic phase transitions in shape-memory alloys: experiments, modeling, and numerical simulation.
Dirk Helm (Fraunhofer IWM Freiburg, Germany) GA/CT3137/007

As a result of martensitic phase transitions, shape memory alloys exhibit a thermomechanical behavior, which cannot be observed in other materials. Therefore, shape memory alloys enable exceptional products like stents, endoscopic devices for minimally invasive surgery, and eyeglass frames. In order to develop and improve such innovative products, the structural behavior must be simulated in the framework of thermomechanics on the basis of experimental investigations.

In the first part of the present contribution, the thermomechanical behavior of shape memory alloys is discussed. Thereafter, the identified material properties are modeled in the framework of continuum thermomechanics. The proposed model is based on a free energy function and evolution equations for internal variables. Thermomechanical consistency is ensured in the sense that the constitutive model satisfies the Clausius-Duhem inequality. Finally, the proposed constitutive theory is numerically treated in the context of the finite element method in order to simulate the behavior of structures made of shape memory materials.

Coupled CFD analysis of hot gas and coolant flow in effusion-cooled combustion chambers. **Jörg Riccius** (DLR Lampoldshausen, Germany), Andreas Gernoth (DLR Lampoldshausen, Germany), Oskar Haidn (DLR Lampoldshausen, Germany) GA/CT3672/007

In order to increase the efficiency of currently available $10\,\mathrm{MPa}$ combustion chambers, hot gas pressures of up to $25\,\mathrm{MPa}$ are desirable. As such high pressures lead to an increased heat transfer from the hot gas into the combustion chamber wall, alternative cooling methods to the conventional regenerative cooling are required. One of the most promising alternative cooling approach is effusion cooling. The advantages of effusion cooling are damage tolerance and a comparatively low weight.

Since a few years DLR works on the field of effusion technology [1,2,3]. In the current abstract / paper, underlying CFD analyses are shown. These CFD analyses are based of the following principles:

- 1-degree 3D model (quasi-2D rotatory symmetric);
- solution of the Navier–Stokes equations;
- coupled analysis of the hot gas and the coolant flow in the combustion chamber (multi species);
- compressible flow;
- real gas;
- SST turbulence model in the combustion chamber and in the combustion chamber wall;
- in the combustion chamber wall: distributed resistance according to Forchheimer.

In a first step, the Forchheimer parameters, which describe the distributed resistance, are determined by means of a least square fit of experimental results with conical test samples. The excellent coincidence between the experimental and the numerical results with the least square fitted parameters confirms the validity of the Forchheimer model.

Based on the least-square-fitted Forchheimer parameters of the conical test samples, a coupled CFD analysis of the hot gas flow in the combustion chamber and the coolant flow in the combustion chamber wall is performed. The detailed analysis of the combustion itself is avoided by defining the injector plate of the combustion chamber as an inlet of the by-product of the combustion (steam). A good comparison between the experimentally and the numerically obtained mass flow rates can be obtained by fitting the turbulence parameters in the area of the porous medium.

Dynamic and microstructural effects in a cylinder induced by the thermal pulse at its face. **Yaroslav Zhuk** (Timoshenko Institute, Kyiv, Ukraine), Olga Chervinko (Timoshenko Institute, Kyiv, Ukraine), Igor Senchenkov (Timoshenko Institute, Kyiv, Ukraine) GA/CT2223/007

Processes of generation and propagation of stress wave caused by the thermal impact at the face of long thin steel cylinder are investigated in the frame of coupled thermomechanics using thermodynamically consistent theory of inelastic material behavior. Dynamic problem statement is used. It is solved by FEM technique developed especially to treat the coupled thermomechanic behavior of inelastic material. Main properties of thermomechanical state in the vicinity of thermal pulse, stress wave propagation accompanied with temperature variation are studied as well as relationship between parameters of the thermal pulse and stress wave.

Microstructural transformations in a cylinder made of martensitic steel induced by the thermal pulse at its face are investigated as well. Material behavior is simulated by the same coupled thermo-viscoplastic model. The model is modified to take account for the microstructural transformations. To calculate the new phase generated under cooling of austenitic state the continious cooling transformation (CCT) diagrams are utilized. The change in microstructural state of martensitic component is accounting by the volume change as well as change of Bodner-Partom model parameters in appropriate way.

Evolutions of structural state and residual strain-stress state as a result of cooling are studied. The cooling regimes causing the formation of residual compressive stresses in the vicinity of the face are determined.

A mortar method for thermomechanically coupled problems. **Elke Berend** (Universität Hannover, Germany), Peter Wriggers (Universität Hannover, Germany), Udo Nackenhorst (Leibniz Universität Hannover, Germany) GA/CT2172/007

The demand for the development of numerical models for thermomechanically coupled contact problems receives impulses from various sectors of the industry. Regarding the foundry industry the final quality of casting products depends on the appearance of residual stresses, warping and size alterations. The numerical prediction of quality defects requires an application of more detailed constitutive material equations and the precise modelling of the cast/mould interaction during the solidification process. Within the latter the contact-dependend heat transfer between the metal and the mould plays a decisive role.

Due to the discrete nature of the constraint enforcement com-

monly used node-to-segment formulations for contact interaction show discontinuities in the transmission of contact pressure. Using the mortar method pointwise constraints across the internal interfaces are replaced by suitable weak continuity conditions which prevent the inconsistencies mentioned above. Within the mortar approach the contact surfaces are connected via Lagrange multipliers which are introduced on the boundaries of the contacting bodies. In this approach an interpolation of these multipliers with dual basis functions is proposed. Due to this choice a degree of freedom reduction is straightforward such that the Lagrange multipliers can be eliminated within a direct solution method. Hence the global system of equations only includes displacement degrees of freedom which leads to more robust algorithms when dealing with semi-solid metal.

Based on this development an extension of this approach to thermomechanically coupled problems is presented including heat conductance and radiation which depend on the contact pressure and the formation of local gaps, respectively.

Physical aspects of mathematical description of the Doppler's effect. **Józef Rafa** (WAT Military University of Technology, Poland), Gawinecki Jerzy Gawinecki (Military University of Technology, Warsaw, Poland) GA/CT1325/007

We present the Doppler effect as a solution to an wave equation concerning waves generated by a moving in space source of the wave that periodically changes itŠs signal in time. The solution has been reached by basing on the Cagniard - de HoopŠs method. The reached conclusion of the analysis proves that the Doppler effect presents the change in the frequency of the received signal as well as the change of itŠs phase. In conclusion these changes are inhomogeitic and anizotropic. This research has been successfully applied in telecommunication and in locating sources of radiation of electromagnetic waves.

GA/CTS4779/07: Ferroelectrics.

Co-organiser: Guenther Meschke (Ruhr-Universität Bochum, Germany)

Micro-electromechanical concepts for modelling ferro- and piezoelectric materials. **Johannes Rödel** (German University in Cairo, Egypt) GA/CT4254/007

Ferro-electric ceramic materials usually show micro-structural features on different length scales. They are polycrystalline solids with crystallites of random crystallographic orientations. The crystallites are divided into ferroelectric domains of differently oriented spontaneous polarizations and associated strains. The domains are crystallographically correlated and form often hierarchical patterns where the grains consist of blocks or bands which in turn consist of a fine domain structure. These domain patterns can change by switching the local polarization and associated strain under sufficiently large applied fields or loads. This leads to a macroscopic behavior of the ceramic material, including non-linear electro-mechanical response and hysteresis, which is very different from local single crystal response.

The aim of micro-electromechanical constitutive models is to describe and to calculate the macroscopic electro-mechanical response of ferroelectric polycrystals on the basis of microscopic properties and simplified micro-structural descriptions of the material. From this point of view, micro-mechanics provides the classical approach to bridge scales within the framework of continuum mechanics.

The present work will demonstrate the usage of simple microstructural models, like laminates and matrix-inclusion-models, to build a complex hierarchical homogenization theory. Within this model, the non-linear behavior of ferroelectrics is a result of changes of the microstructure by moving domain walls and local switching of the ferroelectric polarizations under applied fields.

Simulation of micro-cracking in ferro-electric materials based on a cohesive-type approach. **Johannes Utzinger** (TU Kaiserslautern, Germany), Andreas Menzel (Universität Siegen, Germany), Paul Steinmann (TU Kaiserslautern, Germany) GA/CT1967/007

Ferroelectric materials exhibit a huge potential for engineering applications, ranging from electrical actuators (inverse piezoelectric effect) to sensor technology (direct piezoelectric effect). To give an example, lead zirconate titanate (PZT) is a typical perovskite ion crystal possessing ferroelectric properties. In this contribution, we are particularly interested in the modelling of microcracking effects in ferroelectric materials.

In view of Finite-Element-based simulations, the geometry of a natural grain structure, as observed on the so-called micro-level, is represented by an appropriate mesh. While the response on the grains themselves is approximated by coupled continuum elements, grain boundaries are numerically incorporated via so-called cohesive-type elements. For the sake of simplicity, switching effects in the bulk material will be neglected. The behaviour of the grain boundaries is modelled by means of cohesive-type laws. Identifying grain boundaries as potential failure zones leading to microcracking, cohesive-type elements consequently offer a great potential for numerical simulations. As an advantage, they do not result in bad-conditioned systems of equations as compared with the application of standard continuum elements to localised deformations. Finally, representative constitutive relations for both the bulk material and the grain boundaries, enable two-dimensional studies of benchmark boundary value problems.

A fully-coupled nonlinear thermoelectromechanical model for piezolaminated smart structures. **Sven Lentzen** (RWTH Aachen, Germany), Ruediger Schmidt (RWTH Aachen, Germany) GA/CT1974/007

In present engineering applications piezoelectric materials gain increasing importance in the development of smart structures; e.g., for shape and vibration control problems. Such structures exhibit a three-way coupling effect between the mechanical, electrical and thermal quantities. In the majority of papers available in literature this coupling is taken into account only in the constitutive equations. It is however well known that truly coupled analysis should also be based on the interaction of the mechanical, thermal and electrostatic quantities in the field equations. Only in this way many physical effects can be taken into account; e.g., the strain rate dependant change of temperature due to mechanical loading. Furthermore most of the analyses conducted in this area are performed in the linear range of deformations assuming small strains, rotations and temperature changes. However smart technology is generally applied to thin walled structures and in many cases reported in literature are much large than the thickness, which results into geometrically nonlinear behaviour; like e.g., the occurrence of stress stiffening which greatly affects the prediction of sensor voltage outputs.

The present paper deals with the fully coupled thermoelectromechanical analysis of piezolaminated structures in the sense mentioned above, uncluding the geometrical and thermal nonlinear effects. A thermodynamically consistant contin-

uum mechanics based framework is developed, which includes the conservation of mass, linear and angular momentum and the conservation of energy. The second principle of thermodynamics is used to derive the restrictions for the constitutive equations using Coleman–Noll analysis approach. The resulting set of equations is more general and valid for a wider class of problems than most models published in literature. For the sake of general applicability all equations are derived with respect to convective curvilinear coordinates.

On the piezoelectric shear effect in ultrasonic motors. **Martin Schönecker** (TU Darmstadt, Germany), Ana Conrado (TU Darmstadt, Germany) GA/CT2352/007

A new actuator concept for piezoelectric ultrasonic motors (USM) using the d_{15} effect is considered. Whereas the piezoelectric d_{33} and d_{13} effects are normally used in commercial motors, there exist hardly any USM based on shear actuation. Prototypes existing in the literature are described briefly.

After a short literature review, the paper introduces a new concept for actuation using the d_{15} effect. It is described analytically by deriving and solving the equations of motion for a shear actuator with voltage excitation. An optimization is performed with respect to the dynamic piezoelectric coupling factor. Suitable superposition leads to ultrasonic traveling waves capable of driving a rotor. The feasibility of the concept is demonstrated by a first prototype motor produced in our lab in Darmstadt.

An incremental variational formulation for the coupled electro-mechanical response of piezo-ceramics. **Daniele Rosato** (Universität Stuttgart, Germany) GA/CT4065/007

The paper presents continuous and discrete variational formulations for the treatment of the non-linear response of piezoceramics under multiaxial electromechanical loading. The point of departure is a general internal variable formulation that determines the hysteretic response of the material as a generalized standard medium in terms of an energy storage and a dissipation function. Consistent with this type of standard dissipative continua, we develop an incremental variational formulation of the coupled electromechanical boundary value problem. We specify the variational formulation for a setting based on a of smooth switching-surface which governs the hysteretic response. An important aspect is the numerical implementation of the coupled problem. The discretization of the two-field problem appears, as a consequence of the proposed incremental variational principle, in a symmetric format. The performance of the proposed methods is demonstrated by means of a spectrum of benchmark problems.

Modeling of coupling phenomena in multifunctional materials. **Bjoern Kiefer** (Universität Stuttgart, Germany) GA/CT1775/007

The recent emergence of new active and multifunctional materials, such as ferroelectrics (piezoceramics) and magnetic shape memory alloys (MSMAs), has posed new challenges for constitutive modeling. The complexity of the constitutive response that such materials exhibit is due to its typically nonlinear and hysteretic nature as well as the intrinsic coupling of thermal, mechanical, electric and magnetic effects.

The presented work addresses three different aspects of the modeling process, the formulation of phenomenological constitutive models for MSMAs and ferroelectrics, which are based on an extended thermodynamic framework and utilize internal state variables to capture hysteretic effects and loading history dependence, the numerical implementation of such constitutive models into a finite element environment and the numerical analysis of coupled boundary value problems.

Magnetostrictive actuation of a smart beam with hysteretic material behaviour. **Heiko Bossong** (RWTH Aachen, Germany), Ruediger Schmidt (RWTH Aachen, Germany) GA/CT1715/007

Magnetostrictive materials can be used as actuators in smart structures technology. The relation between induced strain and the applied magnetic field is nonlinear and shows hysteretic behaviour. Thus the magnetomechanical coupling coefficient is not constant and should be defined as a function of strain or magnetic field in computations.

In this study the hysteresis of a mechanically unconstrained actuator is determined using the Michelson interferometry. The hysteretic behaviour is modelled phenomenologically by a Preisach model. Using these experimental data for the modelling of an active structure with embedded magnetostrictive actuators, the actual coupling coefficient can be determined utilising the Preisach model. With this procedure the actuation strain of an embedded actuator, including the physical nonlinearities, can be calculated using the material characteristics obtained with an unconstrained actuator. For the determination of the actual coupling coefficient a strain and field dependent approach is used.

For an experimental validation of the method outlined above, a magnetostrictive actuator is characterised experimentally and then applied to a cantilever aluminium beam. Then, the tip displacement of the actuated beam is measured with a laser triangulation sensor.

Geometrically nonlinear finite-shell elements with magnetostrictive layers. **Ruediger Schmidt** (RWTH Aachen, Germany), Sven Lentzen (RWTH Aachen, Germany) GA/CT1988/007

The area of smart structural control has raised the interest of many researchers in the field of mechanical, electrical, material and control engineering. A relatively small number of material types have proven suitable to be applied as sensors and/or actuators; e.g., piezoelectric and magnetostrictive materials and shape memory alloys. A wide variety of literature can be found dealing with the modelling of piezoelectric materials. Considerably less publications can be found about the latter two materials, especially when geometrical nonlinearity is concerned.

In this paper a geometrically nonlinear composite shell element with integrated magnetostrictive layers is presented. Three translational and two rotational nodal degrees of freedom are used for the first-order transverse shear approximation. The finite element is used in order to investigate shape and stability control problems of structures with magnetostrictive actuator layers in the range of large deformations. The numerical approximations to this static problem are obtained using the total Lagrangian formulation for the moderate rotation shell theory. The aforementioned finite element is used to numerically investigate the actuation behaviour of the integrated magnetostrictive layers. Since the magnetic field is prescribed, the

coupled magnetoelastic problem turns into a decoupled problem. In the final paper a few examples of thin-walled plates and shells with integrated magnetostrictive layers will be presented.

3D multifield modelling of electromagnetic metal forming processes. **Jaan Unger** (Universität Dortmund, Germany), Bob Svendsen (Universität Dortmund, Germany) GA/CT2290/007

Electromagnetic metal forming is a contact-free high-speed forming process in which strain rates of more than 10^3 s^{-1} are achieved. The deformation of the workpiece is driven by a material body force, the Lorentz force, that results from the interaction of a pulsed magnetic field with eddy currents induced in the workpiece by the magnetic field itself.

The purpose of this work is to present a fully-coupled 3D simulation of the process. For the mechanical structure a thermoelastic, viscoplastic, electromagnetic material model is relevant, which is incorporated in a large-deformation dynamic formulation. The evolution of the electromagnetic fields is governed by Maxwell s equations under quasistatic conditions. Their numerical solution in 3D requires particular arrangements due to a reduced regularity at material interfaces. Hence, Nédélec elements are employed. Coupling between the thermomechanical and electromagnetic subsystems takes the form of the Lorentz force, the electromotive intensity, and the current geometry of the workpiece in the electromagnetic domain. A staggered scheme based on a Lagrangian mesh for the workpiece and an ALE formulation for the electromagnetic field is utilized to solve the coupled system, guaranteeing the efficiency and accuracy of the data transfer between the two boundary-matching meshes. This mesh adoption allows for a special data mapping of the strongly decaying Lorentz forces in the thickness direction of the workpiece. In contrast to other simulation examples where continuum elements are applied this data mapping approach allows for the use of highly efficient solid shell elements.

Problem of magneto-elasticity for a solid with the spherical cavity. **Olga Dashko** (Timoshenko Institute, Kyiv, Ukraine) GA/CT934/007

The solution of a static problem of magnetoelastisity for a soft ferromagnetic elastic solid with the spherical cavity is obtained on the base of the linear theory of Brown, Pao and Yeh. It is assumed that the solid has a multi-domain structure, so the hysteretic loss and remanent magnetization are neglected. The solid is affected by a magnetic field which is uniform at infinity and determined by the magnetic induction vector. The cavity causes some distortion of the field distribution near the interface. So the field induces magnetic moments and produces stresses and deformations in the body. The problem is solved for an unperturbed strain state. An approach is discussed to find the perturbed values on the base of the solution obtained. The Fourier variable separation method is used. The stresses are presented via harmonic functions. As a result magnetoelastic stresses are obtained in the closed form. Their distribution in the body is studied and some results of numerical calculations are shown.

Coupled problems in biomechanics and medical technology. **Markus Böl** (TU Braunschweig, Germany), Stefanie Reese (TU Braunschweig, Germany), Daniel Christ (TU Braunschweig, Germany) GA/CT3472/007

The contribution focuses on multi-field problems in the context of applications of biomechanics and/or medical technology. The first example concerns the finite element modelling of sceletal muscles the activation of which can be mathematically described as follows. Based on a distribution function we determine the action potential in dependence of space and time. This action potential leads to an increase of the Calcium concentration. The latter two steps require the solution of two differential equations. It is further noted that the Calcium diffusion is dealt with by introducing another degree-of-freedom at each finite element node. When the Calcium concen-tration reaches a certain limit the muscle contraction begins (single twitch). Finally a summation over the motor units is carried out which gives us finally the mechanical response of a single muscle fibre. The behaviour of the total muscle is computed as discussed in [1]. In medical technology, e.g. to manufacture intracranial stents, the special properties of shape memory alloys and polymers are used frequently. In both cases the structure is able to recover its original state. In the context of shape memory alloys this phenomenon is called pseudo-elasticity or shape memory effect, depending on whether the behaviour is stress- or temperature-induced. Much less well-known is the fact that polymers may also exhibit a so-called shape memory effect which is, however, due to the significant change of material properties in the glass transition range. To describe this phase transition another variable is introduced which can be either (1) directly linked to the temperature, (2) have the status of an internal variable or (3) a field variable. The different possibilities are discussed. Due to the shape memory effect the deformation obtained up to a certain point is "frozen" when the temperature reaches the glass transition range from the above. Heating up the structure beyond the glass transition temperature the orginal state is recovered. This behaviour is exploited e.g. in the context of stents or medical threads. The talk closes with several numerical applications where also aspects as solution methods and coupling strategies are discussed.

Coupled time-domain analysis with boundary and finite elements. **Thomas Rüberg** (TU Graz, Austria), Martin Schanz (TU Graz, Austria) GA/CT2358/007

The numerical analysis of dynamic soil-structure interaction is impeded by the soil half-space surrounding the region of interest. Standard finite element methods (FEM) truncate the mesh and thereby produce artificial wave reflections at the non-physical boundaries. The boundary element method (BEM) does not suffer from this deficiency by an implicit fulfilment of the radiation condition. Nevertheless, it does not provide the robustness and reliability as the FEM when applied to large deformations, plastifications or other non-linear effects.

Therefore, the application of both methods by certain coupling strategies is a well-established means to make use of the respective advantages of the method. So far, iterative coupling

strategies usually depend on some empirically chosen relaxation parameters which are problem-dependent. Therefore, a direct coupling approach is more robust.

A drawback in most coupling strategies is the strong fulfilment of the interface conditions which requires matching interface discretizations. This restriction is too severe when dealing with large substructures, whose meshes are commonly generated independently, and does not obey the different stability criteria for different numerical methods, especially in dynamic analyses.

In this work, an algorithm is presented which allows for different numerical methods (e.g., FEM and BEM) in the sub-domains and is not restricted to conforming interface discretizations. Whereas this idea, similar to the *Mortar* methods, is well-established for the analysis of static problems, it will here be transfered to time-domain problems. This is basically done by formulating so-called Dirichlet-to-Neumann maps in a discrete setting, which can be given by either method, and combining them with Lagrange multpliers in a weak form. Additionally, an efficient solution procedure for the resulting saddle point problems will be proposed for applications to the acoustic wave equation and elastodynamic problems.

Higher-order energy consistent-time integrators for nonlinear thermo-viscoelastodynamics. **Michael Gross** (Universität Siegen, Germany), Peter Betsch (Universität Siegen, Germany) GA/CT1660/007

Although the temporal finite element method is well-known since many years, for the temporal discretisation the finite difference method is still preferred. An advantage of the temporal finite element method is that higher-order accurate time integrators can be constructed easily. A further important advantage is the inherent energy consistency if applied to the equations of motion of dynamical systems [1]. The temporal finite element method is therefore used to construct higher-order energy-momentum conserving time integrators [2]. These time integrators turned out to be well suited for computing motions in nonlinear elastodynamics. Considering finite motions of a flexible solid body with internal dissipation, an energy consistent time integration is also of great advantage (see the references [3,4,5]).

In this presentation, we show that an energy consistent time discretisation is also advantageous for dynamics with dissipation arising from conduction of heat together with internal viscous dissipation. We start by deriving energy consistent fully weak evolution equations for all state variables (configuration, linear momentum, entropy and viscous internal variable) directly from the total energy of the system. The energy consistency is preserved by using a new enhanced hybrid Galerkin (ehG) method. The obtained numerical schemes satisfy the energy balance exactly independent of their accuracy order and the used time step size. This guarantees numerical stability.

Effective parallelized co-simulation of mechatronic systems with subsystems integrated by different methods. **Markus Friedrich** (TU München, Germany), Heinz Ulbrich (TU München, Germany) GA/CT2231/007

This paper describes a method for coupling dynamic subsystems, which are originally independent, by Co-Simulation. This gives the possibility to simulate systems consisting of various domains and simulators. Each subsystem can use a totally different integration method (e.g. ODE, DAE or Time-Stepping) and can even be closed source, because the Co-Simulation is only based on input and output numerical data at the macro time steps. In case of mechanical subsystems the coupling is done on kinetic level by force laws. By introducing a modular master-slave concept it is also possible to parallelize the computational cost of each subsystem, when using a multiprocessor/-core system or even a cluster. The scalability of this parallelization is mainly affected by the overhead of the subsystem communication. On the site of information engineering this problem is to be concerned with PVM, MPI or shared memory techniques for effective and fast inter process communication and synchronization. On mathematically side this is concerned with a higher order discretization of the coupling force to increase the macro step size which also leads to better scalability. Lastly this method is applied on an industrial example in form of a Co-Simulation between a timing chain drive and a valve train.

On coupled problems in geomechanics. **Wolfgang Ehlers** (Universität Stuttgart, Germany) GA/CT4081/007

Geomechanical problems are generally based on the category of granular, cohesive-frictional materials with a fluid pore content. At the macroscopic scale of continuum mechanics, these materials can be successfully described on the basis of the well-founded Theory of Porous Media (TPM) [1].

The present contribution touches fundamental problems of coupled media by investigating the interacting behaviour of an elasto-viscoplastic porous solid skeleton, the soil, and two pore fluids, water and air. Furthermore, electro-chemical reactions are considered in order to include the swelling behaviour of active soil. In conclusion, this leads to a system of strongly coupled partial differential equations (PDE) that can be solved by use of the finite eelment method (FEM). In particular, the presentation includes fluid-flow situations in the fully or the partially saturated range, swelling phenomena of active clay as well as localization phenomena [3,4] as a result of fluid flow or heavy rainfall events. The computations are carried out by use of the single-processor FE tool PANDAS[1] and, in case of large 3-d problems, by coupling PANDAS with the multi-processor solver M++.

A three-phase FE-model for the simulation of partially saturated soils. **Felix Nagel** (Ruhr-Universität Bochum, Germany), Guenther Meschke (Ruhr-Universität Bochum, Germany) GA/CT4069/007

While for many computational analysis in geotechnics use of a two-phase model is sufficient, separate consideration of all three phases is mandatory for numerical simulations of partially saturated soils subjected to compressed air. This is a common technique frequently applied for temporary ground support in tunnelling. For the numerical simulation of tunnelling using compressed air, a multiphase model for soft soils is developed, in which the individual constituents of the soil - the matrix, the fluid and the gaseous phase - and their interactions are considered.The three phase model is formulated within the framework of the mixture theory, based upon balance equations (momentum balance of the mixture, mass balance of the fluid and gaseous phase) and constitutive relations for the soil skeleton, the pressure-density relation of the gaseous phase, the pressure-suction relation and the pressure-seepage flow relation. Water is modelled as an incompressible and air as a compressible phase. The three phase soil model is implemented within an object-oriented FE-code developed for numerical simulations of shield tunnelling. Selected results from 3D simulations of a repair intervention in shield tunnelling with face support accomplished by means of compressed air will be presented.

A numerical model for partially saturated soils. **Günter Hofstetter** (Universität Innsbruck, Austria), Roman Kohler (Universität Innsbruck, Austria) GA/CT3767/007

The contribution deals with the numerical simulation of the behavior of partially saturated soils within the framework of a coupled three-phase model. In contrast to constitutive models for water saturated soils, which are formulated in terms of a single effective stress variable, some fundamental features of partially saturated soils can only be taken into account using two stress state variables. In the present case the employed stress state variables are (i) the Bishop stress tensor with the Bishop parameter being equal to the degree of water saturation and (ii) suction.

Using these two stress state variables, an elastic-plastic cap model for soils with a shear failure surface and a strain hardening cap is extended in order to represent the behavior of partially saturated soils by taking into account the dependence of the evolution of the shear failure surface and of the hardening of the cap on suction.

The capability of the developed constitutive model is demonstrated by the numerical simulation of a series of suction controlled tests, conducted by Macari et al., involving hydrostatic compression tests, triaxial compression tests, conventional triaxial compression tests, triaxial extension tests and simple shear tests. All these tests were conducted at three different values of suction.

Finally, the three-phase FE-formulation with the constitutive model for partially saturated soils is applied to the numerical simulation of a laboratory test, conducted by Klubertanz, in which a sand column is subjected to a few cycles of dewatering and subsequent watering.

Modeling wave propagation in porous media. **Holger Steeb** (Universität des Saarlandes, Germany) GA/CT2441/007

We discuss the acoustic phenomena of propagating waves within empty and fluid-saturated porous media. Linear acoustic models of porous materials were first introduced in the pioneering contributions of M. Biot (1956) and Y. Frenkel (1944). The famous Biot model of a biphasic porous material consisting of material compressible solid and fluid constituents is characterized by three propagating wave types: the shear wave, and, a fast and a slow compressional wave.

In the present contribution, we present an alternative modeling approach based on the thermodynamically consistent Theory of Porous Media. We show, that in the low frequency regime the dispersion relations of the so-called hybrid limit (bulk modulus of the *solid grains* $K^s \to 0$) are identical for both modeling approaches. Furthermore, several extensions towards more sophisticated models are presented. In addition to modeling purposes, we discuss the relating initial boundary value problems with respect to their numerical treatment in Galerkin finite elements and staggered finite difference methods.

Modeling of timing belt's construction. **Grzegorz Domek** (Kazimierz Wielki Univesity of Bydgoszcz, Poland) GA/CT3538/007

Mathematical description of materials used in belts production appeared to come very close to the real characteristics. Some software allow for introduction of real characteristics and in such conditions it is easier to relate to the real conditions in gears with timing belts. Experimental research confirm essentiality of timing pulley construction for cooperation with timing belt. New materials used in belt construction especially composites oblige us for further research of new belts constructions through experimental research.

Modelling multiphase materials: Biot's theory vs. theory of porus media. **Stefan Diebels** (Universität des Saarlandes, Germany), Holger Steeb (Universität des Saarlandes, Germany), Zhiyun Chen (Universität des Saarlandes, Germany) GA/CT1684/007

The behaviour of multiphase materials like fluid-saturated soil, gas-filled foams or biological tissues can be described on a macroscopic scale either by Biot's theory (BT) or by the theory of porous media (TPM). It is shown that both approaches lead to a set of comparable equations which describe the same effects, e. g.which allow for the propagation of a second compressional wave (Biot wave). While Biot's theory is formulated in an intuitive way the theory of porous media is built upon a few axioms. Therefore, a non-linear formulation of the TPM is inherent. Several nonlinear but consistent extensions of the TPM are presented and their physical relevance is discussed. A robust numerical treatment of the resulting equations by space-time coupled Galerkin methods is presented.

Space-time FEM applied to wave propogation in porous media. **Zhiyun Chen** (Universität des Saarlandes, Germany), Holger Steeb (Universität des Saarlandes, Germany), Stefan Diebels (Universität des Saarlandes, Germany) GA/CT1883/007

In the present contribution, we formulate and apply a novel Hybrid Velocity Integration (HVI) scheme [2] to a biphasic mixture model describing the deformation behavior of fluid-saturated porous media. By integrating the displacement-velocity relation implicitly, the governing set of equations can be solved by the first-order Time-Discontinuous Galerkin method (DGT) c.f.[1]. The resulting equation system is solved sequentialy upon a coupled space-time finite element mesh. Inconsistent primary quantities over the time intervals are allowed. Furthermore, unlike the conventional DG penalty method, the continuity is enforced by a natural *upwind* flux. Besides, by adjusting the displacement-velocity integration scheme, the method can be easily identified with an implicit formulation, which stablized the solution immensely.

Numerical examples demonstrate the efficiency of the proposed method in comparison with standard discretization schemes based on the MOL. Furthermore, by applying the numerical solution technique to a so-called hybrid mixture model consisting of a material compressible pore-fluid and a materially incompressible solid constituent, we show, that the (highly attenuated) slow compressional wave (Biot's slow wave) can be calculated efficiently.

A general modeling and numerical analysis framework for coupled processes. **Guenther Meschke** (Ruhr-Universität Bochum, Germany), Sandra Krimpmann (Ruhr-Universität Bochum, Germany), Detlef Kuhl (Ruhr-Universität Bochum, Germany) GA/CT4098/007

The present paper is concerned with a generalized procedure for the modeling and numerical analysis of multiphysics problems in computational structural and computational durability mechanics. The multiphysics model is constituted by generalized balance equations, constitutive laws which may include internal variables and, finally, the formulation of driving forces as function of the gradient of primary variables. As basis for the numerical solution of the fully coupled system of non-linear time dependent differential equations the weak form is formulated and linearized with respect to the primary variables. For the numerical analysis of the coupled system the semidiscretization technique is applied. In particular, a generalized multiphysics finite element with hierarchically generated shape functions is proposed. The time integration of non-linear first order semidiscrete initial value problems is performed by discontinuous and continuous GALERKIN schemes of arbitrary polynomial degree. Within this general modeling and simulation framework specific multifield problems can be implemented only on the GAUSS point level of the proposed general multiphysics element. The functionality of the present modeling and numerical analysis environment will be demonstrated by means of illustrative examples. The application to the life time prognosis of concrete structures subjected to mechanical and chemical attack will be discussed as a particular example in a separate paper [1].

Modeling and numerical analysis of chemo-mechanical damage of concrete within a general multiphysics framework. **Sandra Krimpmann** (Ruhr-Universität Bochum, Germany), Detlef Kuhl (Ruhr-Universität Bochum, Germany), Guenther Meschke (Ruhr-Universität Bochum, Germany) GA/CT4094/007

The paper is concerned with a coupled chemo-mechanical damage model describing the interaction of highly non-linear dissolution and transport processes as well as mechanical damage in cementitious materials. For the purpose of reproducing the local chemical reaction and the additional diffusion exactly on the microlevel, a dissolution-diffusion model is developed within the framework of a general multiphysics model [1]. In particular, the ONSAGER & FUOSS model of electrolyte diffusion in chemically inert porous materials based on the theory of ionic clouds by DEBYE & HÜCKEL is presented. This electrolyte diffusion model is able to represent the electric charged mass transport and covers the ion-ion interaction. Furthermore, a reaction kinetics model for portlandite dissociation due to water attack $Ca(OH)_2 \rightleftharpoons Ca^{2+} + 2\ OH^-$ is investigated. This equation indicates the relevance of the amount of calcium ions within the pore space with regards to the state of chemical equilibrium. The ARRHENIUS equation provides the quantitative basis of the relationship between the activation energy and the rate at which the reaction of this dissolution process takes place. The material degradation due to chemical matrix dissolution and mechanical induced damage is captured by an isotropic scalar damage model with an equivalent strain damage criterion. As a representative example the numerical analysis of the model within a general framework [1] is used for the life time prognosis of a concrete beam subjected to mechanical and chemical attack.

A numerical method to approximate the solutions of non-linear absorption–diffusion equations. **Alexandru Dumitrache** (ISMMA - Bucharest, Romania) GA/CT3135/007

In this paper, it is developed a numerical method in order to approximate the solutions of one-dimensional, non-linear absorption-diffusion equations. The method is tested for accuracy against a linear diffusion equation with a solution that can be written in closed form. Then various types of diffusion and absorption terms to determine which ones produce extinction in finite time are tested. Also the numerical solutions of the one-dimensional, non-linear absorption-diffusion equation and the diffusion-free equation are compared and one find that for the cases tested, the numerical absorption-diffusion solutions are always less than the numerical diffusion-free solutions. Furthermore, we find this is true for the cases tested when there is finite and infinite extinction time. We also look at the open problem where we have slow diffusion and weak absorption but, their combined effect is strong.

Atomistic simulations of the shape-memory effect in Lennard–Jones crystals. **Oliver Kastner** (Ruhr-Universität Bochum, Germany) GA/CT1830/007

We present 2D molecular dynamic simulations with an array of 32 small Lennard-Jones crystals. The individual crystals consist of nested lattices of two atom species. Distinct lattice structures can be identified, interpreted as austenite and (variants of) martensite. Temperature and/or load induced phase transitions between these configurations are observed in the simulations.

In previous work the thermal equation of state of one isolated crystal was investigated [1,2]. The crystal is small and it transforms uniformly between austenite and martensite. In the present contribution we investigate an array of such crystals, which are linked along an axis ("chain"). In this regard, the the individual crystals are interpreted as ideal lattice elements of a larger body. The chain is then investigated in numerical tensile tests under load and under displacement control for different temperatures.

The results show that –assuming simple Lennard-Jones potentials of interaction between atoms– the crystal chain allows for the simulation of the fascinating behavior of shape memory alloys, including pseudo-plasticity, pseudo-elasticity and the shape memory effect. The load/strain behavior of the chain assembly is determined by the collective load/strain response of the individual crystals according to temperature and loading conditions. Pseudo-plasticity appears as the result of martensitic de-twinning of the chain upon axial loading at low temperature. Pseudo-elasticity appears as load induced austenite-martensite transitions at high temperature. The shape memory effect is represented by temperature induced martensite-austenite transitions of the de-twinned, martensitic chain.

Our chain-model is motivated by works on elasto-plasticity that make use of snap springs for modeling the load/strain behavior of one lattice element [3, 4]. While snap springs are bi-stable and cold elements, the crystals in our MD model are tri-stable and thermalized. Thus the MD simulations with the chain qualitatively represent a thermo-mechanical material.

Interaction of point defects in ferroelectrics: parameter identification and simulation. **Oliver Goy** (TU Darmstadt, Germany), Ralf Müller (TU Darmstadt, Germany), Dietmar Gross (TU Darmstadt, Germany) GA/CT3252/007

Ferroelectric materials are used in a wide field of applications and can be found in actuators, sensors and in electronic devices. During the high number of mechanical and electrical load cycles to which the material often is exposed, fatigue phenomena may occur. This involves degradation of the material and a decrease of the electromechanical coupling capability. The causes are assumed to be ionic and electronic charge carriers, later modelled as point defects, which interact with each other, with microstructural elements in the bulk and with interfaces. Accumulation of defects can primarily lead to degradation, or finally to mechanical damage and dissociation reactions.

In order to get a better understanding of the defect accumulation processes, a model based on material forces is used to simulate the interaction of defects in periodic and in infinite cells. Applying reasonable kinetic laws, defect migration is simulated in a deterministic way in order to obtain a general tendency of defect formations. The transversally isotropic material is modelled with linear electromechanical coupling.

The defect parameters used in the continuum model are obtained by fitting the results of molecular dynamics (MD) simulations to the continuous spatial fields. Transferring data from the atomic to the continuum level is a field of active research and no unique solution can be presented. On the atomic level, Coulomb–interaction causes a displacement field incompatible to an elastic solution. In order to solve this difficulty, the volume expansion or contraction of a volume around the defect is used to determine defect parameters.

Stability analysis of thermodynamic lubrication problems in journal-bearing devices. **José Durany** (Universidad de Vigo, Spain), Fernando Varas (Universidad de Vigo, Spain), José Pereira-Pérez (Universidad de Vigo, Spain) GA/CT2456/007

The analysis of thermal effects in hydrodynamic lubrication is very important because the technical advance requires more and more trustworthy and effective industrial devices. In this way, the coupled problem is given by the viscosity influence in the hydrodynamic equation, and the velocity field obtained from pressure gradients that it is introduced in the energy equation. Additionally, the bush and shaft thermal exchange with the external environment must be included in the model.

For the numerical solution a finite-element method (FEM) for the hydrodynamic Reynolds equation with a cavitation model of Elrod–Adams is applied (Durany–Pereira–Varas (2006_a)). Next, the energy equation in the lubricating film is solved by a cell–vertex volume method (Morton–Stynes–Süli (1997)). The advantage of this method lies in the possibility of retrieving second-order convergence. The analysis also takes into account the heat transfer by conduction within the bush and shaft. In the first case the bushing temperature distribution is computed by using a P1 collocation boundary-element method. The extension of this model to describe the evolution problem is quite straightforward (Durany–Pereira–Varas (2006_b)), incorporating a transient term in Elrod–Adams equation and in energy equations. Nevertheless, the adaption of the boundary-element scheme used for the thermal model in the bush is not so easy. A combination of boundary-element and dual-reciprocity methods (DRM) can be used to obtain time-stepping algorithms.

Additionally, a model describing the movement of the shaft must be provided. If the shaft is considered as a rigid body this model will consist of an ODE system (relating acceleration of the center of gravity and the external and pressure loads).

Our numerical experiments of mechanical stability try to clarify both the position of the neutral stability curve and the kind of instabilities by analysing the dynamical response of a journal-bearing system based on the Elrod–Adams equation (that do not impose the location of the cavitated region).

Mathematical and physical aspect of the solution of the Cauchy problem to the system of equation describing nonlocal model of propagation of heat with finite speed. **Gawinecki Jerzy Gawinecki** (Military University of Technology, Warsaw, Poland), Józef Rafa (WAT Military University of Technology, Poland), Jaroslaw Lazuka (Institute of Mathematics and Cryptology Military U, Poland) GA/CT1324/007

A new system of equations describing nonlocal model of propagation of heat with finite speed in three-dimensional space has been considered. At first, using Cagniard de Hoop's method, we constructed the fundamental solution for this system of equations. Basing on the constructed fundamental solution, we obtained the explicit formula for the solution of the Cauchy problem for this system of equation and next, applying the method of Sobolev spaces, we have got the $L^p - L^q$-time

decay estimate for the above solution of the Cauchy problem. Basing on the desired $L^p - L^q$-time decay estimate for the solution of the Cauchy problem for the linearized system of equation, we can prove the existence of the global (in time) solution to the Cauchy problem for the nonlinear system associated with linear one.

Deviation of macroscopic properties as a consequence of nano-scopic surface. **Jens Kruschwitz** (Universität Duisburg-Essen, Germany), Max Setzer (Universität Duisburg-Essen, Germany)

GA/CT3668/007

Every macroscopic model is based on properties of the microstructure of the material which can be deviated from assumptions or basic research measurements. In macroscopic physics and chemistry bulk properties are dominant. That is, these depend on mass and volume as extensive parameters. From a scale below $\approx 0.1\,\mu m$ surface physics and chemistry become all-dominant. Therefore, at least two size regions must be handled separately. We studied experimentally the surface interaction in hardened cement paste between solid gel and nanoscopic pores filled either with air or pore water. The physical interpretation shows that the interaction is so intensive that solid and water cannot be handled separately. Therefore, we characterize the system by naming it solid-liquid gel-system. The aim of this contribution is to connect these forces by a multi-scaling theory with the macroscopic phenomena like isothermal or frost shrinkage.

A novel quasicontinuum method for the seamless transition from atomic to continuum length scales and its application to nanoindentation of single-crystalline materials. **Bernhard Eidel** (TU Darmstadt, Germany), Alexander Stukowski (TU Darmstadt, Germany) GA/CT2394/008

This contribution presents a novel multiscale approach aiming at a seamless transition from the atomic to the continuum description of crystalline solids at zero temperature, which is closely related to the quasicontinuum (QC) method.

A key criterion for the construction of a concurrent multiscale methodology is the seamless transition between different length scales. The original QC formulation[1] does not satisfy this requirement due to nonphysical ghost forces arising at the atomic/continuum interface. These are caused by a general mismatch between a local energy computation in the coarse-grained region (using the Cauchy–Born rule) and the nonlocal atomic description.

The new multiscale approach avoids such ghost forces by sticking to a single fully nonlocal description that is applied in all regions of space. Starting from a lattice statics model, dispensable atomic degrees of freedom are replaced by kinematic constraints as has been done[2]. The total potential energy is approximately computed using a sampling scheme with adaptive resolution. In contrast to[2], where approximate nodal forces are computed, this new approach retains a well defined total potential resulting in conservative forces and a symmetric stiffness matrix. Thus, the present ansatz endows the theory with a variational structure. Moreover, it allows the direct application of standard minimization methods and guarantees the existence of an equilibrium state provided that the total potential has a local minimum. The novel QC method is applied to nanoindentation into an fcc single crystal to showcase its performance.

An atomic-interaction-based continuum model for computational multiscale contact mechanics. **Roger Sauer** (University of California, Berkeley, USA), Shaofan Li (University of California, Berkeley, USA) GA/CT2827/008

A computational multiscale contact mechanics model is proposed to describe the interaction between deformable solids based on the interaction of individual atoms or molecules. The model is formulated in the framework of large deformation continuum mechanics and is based on the homogenizing of the discrete description of a large assembly of interacting atoms. The atomic interaction is distinguished into two different cases: the interaction of atoms within a small neighborhood, and the interaction of atoms over large distances. The former furnishes a constitutive relation for the continuum, like the Cauchy-Born rule, while the latter is used to model the interaction, like contact and adhesion, between distinct bodies. The proposed multiscale contact model is formulated as a variational principle and implemented within the finite element method. Three different implementations are proposed, designed to maintain computational efficiency as the length scale increases. In this respect it is shown, that the proposed contact model can lead to a seamless transition between nanoscale contact mechanics, as modelled by molecular dynamics, and macroscale contact mechanics, as modelled by continuum mechanics.

The multiscale contact model is fully normalized in order to determine its characterizing model parameters. These are used to analyze the physical and numerical behavior of the contact model. In particular the scaling of the model is investigated and studied over a wide range of length scales and material properties. The consistency and accuracy of the three formulations is analyzed by a simple contact patch test. Several numerical examples are used to illustrate the applicability of the proposed model to micro/nano-scale contact/interaction problems. By using a second level of homogenization, it is finally shown, that the proposed model can be applied to macroscale contact problems.

Variational approach to formation of mis-oriented micro-structures in plastic deformation. **Radan Sedláček** (TU München, Germany), Jan Kratochvíl (Czech Technical University, Prague, Czech Republic), Martin Kružík (Czech Academy of Sciences, Czech Republic), Christian Krempaszky (TU München, Germany) GA/CT2152/008

The formation of misoriented dislocation cells in the course of plastic deformation is one of the most distinguished features of the deformation-induced microstructures. The cells are separated by dislocations assembled in boundaries that accommodate the resulting mismatch in lattice rotations. The formation of the misoriented cells is explained within the framework of continuum mechanics as a result of the trend to reduce the energetically costly hardening in multislip by locally decreasing the number of active slip systems by local lattice rotations. This explanation is broadly accepted and supported by Finite Element simulations of crystal plasticity where a dominant secondary hardening leads to a grain subdivision. However, an analytically tractable model of the misoriented cell formation that takes into account dislocation mechanisms responsible for the size of the cells and orientation of the boundaries is still lacking.

We present a model of an infinite crystal deformed in plane strain by symmetric double slip, where the plastic strain is carried by straight, parallel edge dislocations. The variational formulation of the incrementally-linear rigid-plastic approximation to crystal plasticity establishes a link to the mathematical theory of non-convex energy minimization. It is shown that a microstructure consisting of a superposition of two periodically arranged sets of parallel deformation bands separated by sharp dislocation boundaries tends to minimize the energy functional by developing a finer and finer microstructure [Sedláček and Kratochvíl, Z. Metallkunde 96 (2005) 602]. The proof that the deformation bands separated by sharp boundaries are energetically favourable has been furnished only recently [Kružík *et al.* in preparation]. The proof relies on the quadratic structure of the corresponding energy functional expressed in terms of the deformation gradient and on the relaxation theory of the variational calculus [Ball and James, Arch. Rat. Mech. Anal. 100 (1987) 13]. In a further development, by considering dislocation interactions, we introduce an internal length-scale into the model that leads to a finite size of the cells as well as to a specific orientation of the deformation bands [Kratochvíl *et al.*, Phys. Rev. B, submitted].

Short-range interactions in the continuum dislocation-based model of plastic deformation. **Cornelia Schwarz** (TU München, Germany), Radan Sedláček (TU München, Germany), Ewald Werner (TU München, Germany) GA/CT2182/008

We present the latest development of the continuum dislocation-based model of plastic deformation at the micrometer scale that was enhanced by considering short-range dislocation interactions.

The model describes the size-dependent behaviour of materials with microstructure (e. g. composites) or of micrometer-scaled samples (e. g. thin films). The size-dependence in the original model [Sedláček *et al.*, Phil. Mag. 83 (2003) 3735] was solely due to the non-locality related to the line tension of the curved dislocations. The line-tension represents the strongest and always present short-range dislocation interaction. To overcome the problem of averaging that appears in the continuum theory of dislocations, the concept of single-valued dislocation fields was introduced. Utilizing crystal plasticity, the description of the evolving single-valued fields of continuously distributed curved dislocations has been coupled with a small-strain continuum mechanics framework. The coupling accounts for the long-range elastic dislocation fields. The resulting system of partial differential equations is a convection-diffusion problem with dominating convection that is solved numerically by means of the so-called dislocation-Lagrangian method developed by Sedláček *et al.* [Phil. Mag. accepted]. This is a numerical technique that enables a stable solution of the considered problem by tracking individual segments of representative dislocations in time.

Recently, the model has been enhanced by considering other short-range dislocation interactions, namely, the mutual interactions between dislocations. To this end, by generalizing the result of Groma *et al.* [Acta Mater. 51 (2003) 1271], we consider gradients of dislocation density perpendicular to the local dislocation line direction. The resulting back stress modifies the size dependence of the modeled material behaviour and improves the numerical features of the resulting convection-diffusion problem.

We present results of several applications of the enhanced model which has been implemented for applications to two-dimensional plane-strain problems, where the continuum-mechanics part is solved by the Finite Element Method. Physical as well as mathematical consequences of the introduction of the back stress representing the short-range dislocation interactions in the model will be discussed.

On the relevance of discreteness in the continuum modeling of dislocation interactions. **Anish Roy** (TU Eindhoven, The Netherlands) GA/CT3194/008

In metals, plastic deformation is mainly attributed to the motion of a large number of discrete defects, namely dislocations. Continuum frameworks of dislocation based plasticity are gaining prominence in the mechanics research (Acharya and Bassani, 2000; Arsenlis et al., 2004). In a continuum setting, dislocation distributions are represented by an averaged continuous description of signed dislocation density. The long range stress interactions are taken care of in a mechanistically rigorous sense. However, the short range interactions between the individual dislocations are either neglected or modeled phenomenologically (Acharya and Roy, 2006).

Completely averaging out the short range interactions bears its ramifications in the overall response of plastic behavior in crystals, for instance in the prediction of pile-ups at grain boundaries. It is realized that these interactions play an important role in dislocation evolution and the lack of collective accounting of such interactions becomes quite significant. Groma et al., 2003 realized the importance of correct characterization of the short range interactions in a continuum setting and attempt to do so in a statistical mechanics framework.

We use a deterministic analysis of an idealized dislocation pile-up against an obstacle to study the current shortcomings in crystal plasticity frameworks. It is realized that the underlying discreteness of the dislocation pattern matters but there is a directional dependence of the discreteness. Based on these observations we attempt to develop a rigorous, physically motivated, continuum description of dislocation mechanics which accounts for both the long-range and short-range interactions accurately.

Mechanical anisotropies of textured polycrystalline metals. **Thomas Böhlke** (Universität Karlsruhe, Germany), Katja Jöchen (Universität Karlsruhe (TH), Germany) GA/CT2641/008

Polycrystalline metals are random heterogeneous media the microstructure of which can be described by n-point probability functions[3]. If these functions are translationally invariant or rotationally invariant the material is either called statistically homogeneous or statistically isotropic. Anisotropies of the macroscopic mechanical behavior are caused by statistically non-isotropic microstructures. They are of significant importance in mechanical engineering as well in materials science. In the presentation we discuss the combination of the aforementioned statistical approach with classical concepts of continuum mechanics. Special emphasis is given to bounds and estimates of effective mechanical properties based on orientational averages (see e.g.,[1,2]). Both, elastic and inelastic properties are considered.

Micromechanical and macroscopical hardening modeling as basis for the realistic simulation of sheet forming processes with complex strain-path changes. **Vladislav Levkovitch** (Universität Dortmund, Germany), Bob Svendsen (Universität Dortmund, Germany) GA/CT3302/006

Sheet metal forming involves large strains and severe strain-path changes. Large plastic strains lead in many metals to the development of persistent dislocation structures resulting in strong flow anisotropy. This induced anisotropic behavior manifests itself in the case of a strain path change by very different stress-strain responses depending on the type of the strain-path change. While many metals exhibit a drop of the yield stress after a load reversal, some metals show an increase of the yield stress after an orthogonal strain-path change (so-called cross hardening). To model the Bauschinger effect, kinematic hardening has been successfully used for years. However, the usage of the kinematic hardening leads automatically to a drop of the yield stress after an orthogonal strain-path change contradicting tests exhibiting the cross hardening effect. Another effect, not accounted for in the classical elasto-plasticity, is the difference between the tensile and compressive strength (SD effect), exhibited e.g. by some steel materials. In this work we first present a micromechanical model

that takes into account the evolution of polarized dislocation structures on the grain level, the non-Schmidt effect for the dislocation slip resistance and texture evolution. The micro-macro transition is performed via the Taylor hypothesis. The model is used to investigate the evolution of the yield surface. From these investigations we derive a macroscopic model that considers besides the movement of the yield surface and its proportional expansion, as it is the case in conventional plasticity, also the changes of the yield surface shape (distortional hardening) and accounts for the pressure dependence of the flow stress. All these additional attributes turn out to be essential to model the stress-strain response of high-strength steels subjected to non-proportional loading. The model is applied to predict the spring-back in processes with complex strain-path changes.

Non-local numerical homogenization scheme. **Ralf Jaenicke** (Universität des Saarlandes, Germany), Holger Steeb (Universität des Saarlandes, Germany), Stefan Diebels (Universität des Saarlandes, Germany) GA/CT2158/008

The numerical treatment of multiscale models is of built on the so-called FE^2 concept; i.e., a testing volume consisting of a certain microstructural elements is attached to the integration point of a macroscopic finite element model. The local strain at the integation point is mapped onto the boundary of the testing volume, and, after solving the local boundary value problem, the macroscopic stresses are computed by a homogenization procedure applied to the local problem. In the present contribution the testing volume is assumed to be of small but finite size and, therefore, the local boundary value problem is directly derived from the displacement solution within the finite element. The stresses are computed by an appropriate homogenization scheme and extrapolated to the macroscopic integraton points. In the limit, if the testing volume reaches the size of the finite element, the proposed method becomes similar to domain decomposition methods and the local structure is resolved explicitly.

Towards the computational homogenization of discrete microstructures. **Sarah Ricker** (TU Kaiserslautern, Germany), Andreas Menzel (Universität Siegen, Germany), Paul Steinmann (TU Kaiserslautern, Germany) GA/CT2270/008

The past years have been marked by a growing significance in multi-scale mechanics. This interest is founded on the fact that the concept of pre-assumed (overall) material parameters, or rather constitutive relations, cannot reflect all features of a material with underlying (heterogeneous) continuous or discrete microstructure.

The computational homogenization scheme provides an effective tool to bridge different length scales between the micro- and the macro-level for both continuous and discrete microstructures.

The considered macroscopic specimen is studied by means of finite-element methods, while the associated underlying microscopic setting in each Gauss point is – in the discrete case at hand – identified with so-called mass-spring networks. Furthermore, the influence of different boundary conditions on the micro-level, e.g. linear displacements, periodic displacements and antiperiodic tractions, or constant tractions, on the behavior of the macroscopic specimen is investigated.

Computational micro–macro transitions at large strains for curvilinear physical directions. **Rafael Grytz** (Ruhr-Universität Bochum, Germany), Guenther Meschke (Ruhr-Universität Bochum, Germany) GA/CT2360/008

Biological tissues such as those involved in the eye, heart, veins or arteries are heterogeneous on one or another spatial scale and can undergo very large elastic strains. Frequently, these tissues are characterized by shell-like structures at the macroscopic scale and the physical material directions follow curvilinear paths. We consider a homogenized macro-continuum formulated in curvilinear convective coordinates with locally attached representative micro-structures. Micro-structures attached to different macroscopic points are assumed to be rotated counterparts according to the curvilinear path of the physical material directions at the macro-scale. The solution of such multi-scale problems according to the computational homogenization scheme[1,2,3] would need a different RVE at each macroscopic point.

The goal of this paper is to use the same initial RVE at each macroscopic point by generalizing the computational homogenization scheme to a formulation considering different physical spaces at the micro- and macro-scale. The deformation and the reference frame of the micro-structure are assumed to be coupled with the local deformation and the local reference frame at the corresponding point of the macro-continuum. For a consistent formulation of micro-macro transitions *physical reference directions* are defined on both scales, where the macroscopic one follows a curvilinear path. To formulate the generalized micro-macro transitions in absolute tensor notation the operations *scale-up* and *scale-down* are introduced.

The proposed formulation considering curvilinear physical directions at the macro-scale as well as geometrical and material nonlinearities is demonstrated by means of a multi-scale analysis of a spherical shell structure. This example is characterized by a finite-element discretization of the macro-continuum by means of a bilinear finite shell element with a quadratic kinematic assumption in thickness direction[4], where the integration through the thickness is carried out numerically. A finite element discretization of the same initial micro-structure is attached to each integration point of these macro-elements. The micro-structure is modeled by means of trilinear brick elements.

On the simulation of textile-reinforced concrete using a multi-scale approach. **Ingolf Lepenies** (TU Dresden, Germany), Mike Richter (TU Dresden, Germany), Bernd Zastrau (TU Dresden, Germany) GA/CT3351/008

Textile reinforced concrete (TRC) is a composite of rovings (bundles of endless fibers) and fine grained concrete which is used in the field of civil engineering for the fabrication of new structural elements and the strengthening of existing constructions.

Experimental investigations on textile reinforced concrete samples show very complex failure mechanisms on different length scales. Therefore descriptions on the micro, meso and macro scale are introduced. The presentation shows a hierarchical material model of textile reinforced concrete.

Due to the small dimensions of the filaments and the partial impregnation of the roving within the cementitious matrix a detailed study of the load transfer mechanism on a micro scale under consideration of individual filaments and adhesive cross linkages has been investigated.

To simulate the material behavior of textile reinforced concrete on a larger scale a homogenization is required to reduce the numerical costs. Therefore idealized roving models are developed. The aim of the micro/meso homogenization is an effective roving model to simulate the relevant load transfer mechanisms.

On the so called meso scale a multi-axial textile structure made rovings is modeled. This allows the evaluation of effective material parameters of the analyzed domain in three dimensions by means of numerical and analytical homogenization techniques. One benefit of the used model is the determination of the initial and induced type of material symmetry.

Based on this hierarchical material description and the scale bridging between the different scales a multi-scale Finite-Element-Methods (MS-FEM) of a sequential and integrated type are used.

Numerical analysis of uncertainties in the effective material behaviour of disordered structural foams. **Jörg Hohe** (Fraunhofer IWM Freiburg, Germany), Volker Hardenacke (Fraunhofer IWM Freiburg, Germany) GA/CT1844/008

Solid foams are important materials in many fields of modern lightweight construction. The main advantages of this class of materials is their low specific weight in conjunction with their ability to perform additional, non-mechanical functions such as e.g. heat insulation. Disadvantage is the disordered random microstructure leading in many cases to a distinct variability in the macroscopic material parameters.

The present contribution is concerned with a numerical analysis of the uncertainties in the structural response of three-dimensional structural foams with partially open cells. The effective thermo mechanical material response is determined by means of an energy based homogenization procedure using the finite element method for the microstructural analysis. Stochastic effects in the geometry and topology of the microstructure are treated by means of a Monte-Carlo approach in conjunction with a repeated analysis of small-scale representative volume elements with prescribed relative density and prescribed cell size distribution. The results are evaluated by stochastic methods in order to determine the probability distribution of the effective material parameters. Meso scale variations in the relative density and the cell size distribution are included by a direct stochastic approach.

The approach is applied to the effective elastic, plastic and thermal material parameters of aluminum foams with different nominal relative densities. Strong effects of the microstructural disorder are observed especially with respect to the mechanical strength of the material on the macroscopic level, where both, the expectation and the variance of the material properties are strongly affected by the microstructural disorder. The numerical results are found in good agreement with experimental data from the literature.

Local stochastic analysis of the effective material response of disordered two-dimensional model foams. **Volker Hardenacke** (Fraunhofer IWM Freiburg, Germany), Jörg Hohe (Fraunhofer IWM Freiburg, Germany) GA/CT1932/008

Solid foams are important materials in many fields of modern lightweight construction. The main advantages of this class of materials is their low specific weight in conjunction with their ability to perform additional, non-mechanical functions such as e.g. heat insulation. Disadvantage is the disordered random microstructure leading in many cases to a distinct variability in the macroscopic material parameters.

In order to comply with this problem, a stochastic homogenization procedure is proposed. The procedure is based on the multiple analysis of a medium scale representative volume element consisting of a relatively low number of cells. The representative volume element is subdivided into a number of (non representative) subcells, each consisting of a single cell wall intersection and the corresponding cell walls. For each of the subcells, the average stress and strain states are determined using a strain energy based homogenization procedure. For comparison, an analysis based on the randomization of a regular periodic microstructure is performed.

The disordered microstructure for the representative volume element are determined automatically based on a Voronoi tessalation of the area of the RVE. Different approaches are used, including Γ- and δ-Voronoi techniques, closed-packing-of-spheres models in conjunction with a Laguerre-Voronoi approach, foam evolution models and optimization strategies in order to obtain realistic computational models.

The results of the homogenization analysis are evaluated by means of stochastic methods. Distinct effects of the microstructural disorder are observed. Compared to an idealized regular periodic foam model, the microstructures in general become weaker, if the microstructural disorder is taken into account.

Constitutive modelling of interpenetrated metal ceramic composites with evolving anisotropy. **Felix Fritzen** (Universität Karlsruhe (TH), Germany), Eckart Schnack (Universität Karlsruhe (TH), Germany) GA/CT2141/008

Several phenomenological aspects concerning the constitutive modelling of class interpenetrated $Al - Al_2O_3$ metal-ceramic composites undergoing quasistatic thermo-mechanical loading are presented. The heterogeneous a-periodic microstructure of the material motivates a two-scale incremental treatment of its deformation behaviour. The initial phase of constitutive modelling is devoted to phase-specific formulation of the constitutive response on micro scale in terms of incremental quasihyperelastic potentials [1]. In this context, the inelastic behaviour of the metal phase is described by a J_2-flow rule with isotropic exponential hardening and a multiplicative thermal softening function. Latter accounts for the thermal softening of Aluminium at high temperatures. A smeared crack model is used to depict the quasi brittle damage behavior of the Al_2O_3 ceramic constituent following the conceptual line pointed out in [2]. This model allows for a developping anisotropy of the mechanical properties of the ceramic constituent due to a degradation of the material stiffness tensor by the onset of inelasticity. Thermodynamical consistency is granted for both models. Unilateral effects are also considered in the constitutive model. At this stage both models are limited to rate-independent deformation processes.

Zweiskalensimulation von Schädigungsprozessen in unidirektional faserverstärkten Verbundwerkstoffen. **Benjamin Köster** (Universität Kassel, Germany) GA/CT2227/008

Bei der Beanspruchung von Verbundbauteilen bis in den Bereich der Werkstoffschädigung handelt es sich um komplexe, gekoppelte Vorgänge auf unterschiedlichen Längenskalen. Die mittlerweile verfügbare Rechnerkapazität ermöglicht die gleichzeitige Mehrskalensimulation derartiger Prozesse. Bei der hier unternommenen Zweiskalensimulation von Faserverbundstrukturen wird die Makroskala durch die Ebene der strukturmechanischen Bauteile oder Bauteilkomponenten definiert. Die Mikroskala ist durch die typischen Abmessungen der Heterogenitäten des Verbundwerkstoffe bestimmt. Das Ziel der gekoppelten Mikro-Makro-Analyse ist die realitätsnähere strukturmechanische Simulation auf Basis einer detaillierteren Betrachtung der Vorgänge auf der Mikroebene des Werkstoffs. Die Makroskala wird durch übliche Ansätze der FE-Methode modelliert. Zur Beschreibung der Mikroskala wir eine repräsentatives Volumenelement (RVE) des inhomogenen Gefüges betrachtet. Die Mikrofelder der Spannungen und Verzerrungen im RVE sind die Lösung einer Randwertaufgabe, die für das Volumenelement formuliert wird. Die verallgemeinerte Methode der Zellen (engl. Generalized Method of Cells, kurz: GMC) liefert eine Näherungslösung für das diskretisierte Verformungsfeld im RVE. Als geometrische Randbedingungen dienen die Verzerrungen der Makroskala. Unter Einbringung geeigneter Konstitutivmodelle in das Zellenmodel für die Phasen und deren Verbund können dann die zu den Makrodehnungsprozessen gehörigen Mikrofelder der Verzerrungen und Spannungen berechnet werden. Das makroskopische Werkstoffverhalten wird durch einen prozessabhängigen Konstitutivtensor beschrieben, der die Abbildung zwischen den volumengemittelten Mikrofeldern der Spannungen und Verzerrungen im repräsentativen Volumenelement leistet. Das mikromechanische Modell liefert als Ergebnis sowohl den konsistent linearisierten, konstitutiven Tensor als auch die makroskopische Spannungsantwort in jedem numerischen Integrationspunkt des Makrostrukturmodells. Der Homogenisierungsalgorithmus der Zellenmethode läuft simultan zur FE-Analyse ab.

Study of wave dispersion in periodic composites by higher-order asymptotic homogenization method. **Vladyslav Danishevskyy** (Prydniprovska State Academy, Ukraine), Igor Andrianov (RWTH Aachen, Germany), Vladimir Bolshakov (Prydniprovska State Academy, Ukraine), Dieter Weichert (RWTH Aachen, Germany) GA/CT2871/008

In the present work an application of the higher-order asymptotic homogenization method (AHM) to the study of wave dispersion in periodic composite structures is considered. It should be noted that the most significant and practically important phenomena caused by the heterogeneity of the composite media arise in dynamic problems. When the wavelength of a travelling signal becomes comparable to the size of heterogeneities, successive reflections and refractions of the waves at the componentsŠ interfaces lead to the formation of a complicated sequence of so called pass and stop frequency bands. In this case the composite plays a role of a discrete frequency filter.

As illustrative examples we study propagation of harmonic elastic waves in a layered composite (one-dimensional problem allowing the exact analytical solution) and in a fibre-reinforced composite with the square array of cylindrical inclusions (two-dimensional problem). The asymptotic homogenization schemes are developed and the higher-order macroscopic wave equations are derived. Analysis of the obtained solutions shows that the AHM provides a long-wave approach valid in the low frequency range. Solutions for the high frequencies are obtained on the basis of the Floquet-Bloch theorem by expanding spatially varying material properties in Fourier series and representing unknown displacement fields by infinite plane-wave (PW) expansions. However, this approach may run into convergence problems with the increase in contrast between the components properties. Eventually, we can conclude that the higher-order AHM and the PW expansions method can be treated as complementary to each other. The dispersion curves relating the wave numbers and frequencies are obtained; the pass and stop frequency bands are identified; the attenuation factors within the stop bands are evaluated.

Well-posedness of infinitesimal gradient-plasticity. **Patrizio Neff** (TU Darmstadt, Germany) GA/CT2494/008

I derive a model of infinitesimal isotropic gradient plasticity. The second law of thermodynamics is modified to include an extra entropy flux. Boundary conditions for the plastic variable are nonstandard.The higher plastic gradient consists only of the dislocation density tensor. Kinematical hardening is included.The flow law turns into a second order parabolic evolution equation. Assuming monotonicity of the flow function it is possible to show well-posedness of the model in a novel Hilbert-space setting which incorporates the Dislocation density

Phase-field simulations on the interaction of ferroelectric domain structures with point defects. **Bai-Xiang Xu** (TU Darmstadt, Germany), David Schrade (TU Darmstadt, Germany), Ralf Müller (TU Darmstadt, Germany), Dietmar Gross (TU Darmstadt, Germany) GA/CT1441/008

It is suspected that point defects and their agglomerates lead to the electric fatigue in ferroelectric materials. In this work, the interaction of ferroelectric domains with point defects and their agglomerates is simulated, using a continuum phase-field model. Expanding the energy of the system by a phase separation and a domain wall contribution and regarding the polarization as an order parameter, the model has successfully revealed typical behavior of ferroelectrics. This includes the formation of domain structures, the migration of domain walls, the dielectric and butterfly hysteresis loops and the ferroelastic switching. To model point defects, such as foreign atoms and vacancies, an inelastic eigenstrain and a localized volume charge are introduced.
Calculations show the hindering effect of defects on the domain wall movement. A delay by defects in the microstructure evolution is also observed. Finally, the influence of point defects on the ferroelectric hysteresis loops is studied. It is demonstrated that the presence of defects apparently hinders the polarization switching and changes hysteresis in a characteristic manner. Results of the simulations show good agreement with experimental phenomena reported in the literature.

Homogenization of special GFRP truss-type elements. **Janko Kreikemeier** (Universität Magdeburg, Germany) GA/CT4026/008

The paper deals with the numerical homogenization of the effective material properties of special glass fibre reinforced truss type elements called Polystal Profiles. The commercial available profiles are made from longitudinal aligned glass fibres embedded in an epoxy resin. The diameters of the cross sections ranges from 1 mm to 16 mm. Originally designed for the strain release of submerged lying optical cables we see other fields of application like the reinforcement of hollow section profiles to exploit the material properties and to improve the loading behaviour. For this purpose we used the method of representative volume element (RVE) to estimate the effective material properties by applying periodic boundary conditions (PBC). To create the RVE a FORTRAN program was developed to get a RVE with a randomly fibre arrangement above the cross section. Furthermore an ANSYS script was created for the meshing and the application of the PBC on the RVE automatically. The obtained results are discussed with respect to experimental values of the longitudinal Youngs-Modulus estimated in earlier works.

Lower-semicontinuity result for the two-scale convergence. **Mahdi Boukrouche** (Université Saint-Etienne, France) GA/CT2533/008

The aim of this talk is to prove the following result, using some results on subdifferential and regularization of convex functions: Let $\Omega \subset \mathbb{R}^m$ an open bounded domain, $Y = [0,1]^m$, and $\varphi : \Omega \times \mathbb{R}^m \times \mathbb{R}^n \to \mathbb{R}$ such that the following hypotheses hold:
(H1) $\varphi(x, \cdot, \cdot)$ is continuous a.e. for $x \in \Omega$,
(H2) $\varphi(\cdot, y, z)$ is measurable for all $(y, z) \in \mathbb{R}^m \times \mathbb{R}^n$,
(H3) $\varphi(x, \cdot, z)$ is 1-periodic in y,
(H4) $\varphi(x, y, \cdot)$ is convex in z,
(H5) $\exists C_1 > 0$ and $\exists C_2 \in L^2(\Omega)$ such that
$|\varphi(x, y, z)| \le C_1 \|z\|^2 + C_2(x) \quad a.e. \quad x \in \Omega \quad \forall (y, z) \in \mathbb{R}^m \times \mathbb{R}^n$

Let u^ε in $(L^2(\Omega))^n$ which two-scale converges to some u in $(L^2(\Omega \times Y))^n$, and φ such that (H1)–(H5) hold. Then we have

$$\liminf_{\varepsilon \to 0} \int_\Omega \varphi(x, \frac{x}{\varepsilon}, u^\varepsilon(x)) dx \ge \int_\Omega \int_Y \varphi((x, y, u(x, y)) dy dx .$$

On dispersive stability of Hamiltonian systems on lattices. **Carsten Patz** (Weierstraß-Institut Berlin, Germany) GA/CT2890/008

We study the long-time dynamics of *oscillations in lattices of infinitely-many particles* interacting via certain nonlinear potentials. In particular we consider the Klein-Gordon system on the infinite chain and the two dimensional lattice. The aim is to proof *dispersive stability* of such Hamiltonian systems analogously to results known for PDEs.

To do so we first recapitulate the dynamics of linear Hamiltonian systems on an infinite chain and give optimal decay rates based on the dispersion relation. We will also discuss the two dimensional lattice with nearest-neighbour interaction where more complicated singularities occur.

Based on this we proof that if the nonlinearity is weak enough, the Klein-Gordan system shows a similar behaviour like its linearisation.

Up-scaling in nonlinear thermal-diffusion problems. **Claudia Timofte** (University of Bucharest, Romania) GA/CT4184/008

The general question which will make the object of this paper is the homogenization of some nonlinear problems arising in the modelling of thermal diffusion in a two-component composite. We consider, at the microscale, a periodic structure formed by two materials with different thermal properties. We shall consider two situations: in the first one, we assume that we have some nonlinear sources acting in both components and that at the interface between our two materials the temperature and the flux are continuous, while in the second problem we shall address here, we assume that the flux is still continuous, but depends in a nonlinear way on the jump of the temperature field. In both cases, since the characteristic sizes of these two components are small compared with the macroscopic length-scale of the flow domain, we can apply an homogenization procedure.

Using the so-called energy method introduced by L. Tartar, in the first case we can prove that the limit problem will be a new nonlinear elliptic boundary-value problem with extra zero-order terms capturing the effect of the nonlinear sources acting in our two parts of the domain. The asymptotic behavior of the solution of the second problem will be governed by a new nonlinear system, similar to the famous Barenblatt's model, with extra zero-order terms capturing the effect of the interfacial barrier and of the nonlinear sources.

Comparison of phenomenological theories with physically-based theories of plasticity. **Vladimir Shneider** (Dnipropetrovs'k National University, Ukraine), Yuriy Chernyakov (Dnipropetrovs'k National University, Ukraine) GA/CT619/008

The theory of plasticity, including micro strains [1,2], considers heterogeneity of representative macro volume of polycrystalline material by introduction of micro particles with various yield stresses and various directions of micro plastic deformation. These micro particles can interact and affect macroscopic stress-strain state. In theory the generalization of physical approaches to the description of plastic deformation (Schmid law) realized and invariant approach displaying transition to higher scale level (from a level of dislocation sliding up to a level of micro plastic deformation of grain) is applied. It was shown [2], that the theory of micro strains is reduced to many known *physical* theories of plasticity in special cases. In this paper comparison of the theory of micro strains with the theories based on physically reasonable slip mechanisms of plastic deformation is carried out. Benefits and shortcomings of the offered invariant approach are analyzed.

Energy functionals for microstructured multi-phase materials. **Tom-Alexander Langhoff** (Universität Karlsruhe (TH), Germany), Thomas Böhlke (Universität Karlsruhe, Germany), Eckart Schnack (Universität Karlsruhe (TH), Germany) GA/CT2197/008

Many state-of-the art materials (e.g., carbon fibre reinforced carbon, CFC) show a multi-phase and a multi-scale character. For describing the material response, energetic models have been developed for a wide range of problems in many of which the energy functionals are no longer convex [1]. Restrictions on the energy functionals arise in order to obtain existence results for rate-independent systems [2]. In this contribution, we propose an energetic model for describing the thermomechanical response of CFC based on the influence of the microstructure on different length scales [3]. The different phases are given by different textures of the deposited pyrolytic carbon [4]. Based on experimental observations using transmission electron microscopy [5] showing sharp interfaces between the different phases, an interfacial part relaxing the total free energy is included in the energy functional. Further restrictions to the energy functional result from homogenisation to macroscale and phase transformations that possibly occur especially due to thermal loading.

A variational formulation of non-local materials with microstructure based on dual macro- and micro-balances. **Fabian Welschinger** (Universität Stuttgart, Germany), Dominik Zimmermann (Universität Stuttgart, Germany), Christian Miehe (Universität Stuttgart, Germany) GA/CT4006/008

We investigate a variational setting of nonlocal materials with microstructure and outline aspects of its numerical implementation. Thereby, the current state of the evolving microstructure is described by a set of order parameters. These order parameters represent independent global degrees in addition to the macroscopic displacement field. Fokussing on so-called standard-dissipative materials, the constitutive response is governed by two fundamental functions for the energy storage and the dissipation. Based on these functions, a global dissipation postulate is introduced. Its exploitation in the sense of a Coleman method constitutes a global variation formulation of nonlocal materials, which can be related to a minimization principle. Following this methodology, we end up with coupled macro- and microscopic field equations and corresponding boundary conditions. Thereby, we observe a strict duality between a macro-balance in terms of the displacment field and a micro-balance in terms of the order parameter field. On the numerical side, we consider the weak counterpart of these coupled field equations and obtain after linearization a fully coupled system for increments of the displacement and the order parameters. Due to the underlying variational structure, this system of equations is symmetric. In order to show the capability of the proposed setting, we specify the above outlined scenario to a model problem of isotropic damage mechanics and a class of single slip crystal plasticity. The performance of the symmetric coupled formulation is demonstrated by means of a set of representative numerical examples.

Micro-roughness effects in (elasto)hydrodynamic lubrication including a mass-flow preserving cavitation model. **Sébastien Martin** (Université Paris-Sud, France), Carlos Vázquez Cendón (Universidade da Coruña, Spain), Guy Bayada (INSA Lyon, France) GA/CT3491/008

An average Reynolds equation is proposed for predicting the effects of deterministic periodic roughness of the surfaces, taking JFO mass flow preserving cavitation model and elastohydrodynamic effects into account. Thus, the influence of the roughness effects over thin films flows is studied when taking into accound several nonlinearities : cavitation phenomena, piezoviscosity of the fluid, elastic deformation of the surfaces (Hertz model) due to high peak pressures.

For this, the asymptotic model is based upon a double scale analysis approach (multiscale homogenization and periodic unfolding methods) in order to describe the micro-macro effects and derive in a rigorous way the asymptotic equations. The average Reynolds equation can be used both for the description of cavitation on a macroscopic scale in widening gap regions as well as for cavitation on the microscopic interasperity scale.

Results of numerical simulations based on the model are presented for the case of a hydrodynamically lubricated journal bearings and an elasto-hydrodynamically lubricated point contact.

Improved constitutional relations by and for multiscale models. **Heike Emmerich** (RWTH Aachen, Germany) IC/CT3306/008

Constitutional relations are of great impact in materials modeling. Their accuracy determines to a large extend the accuracy at which the the macroscopic behaviour of a material can be described in a respective continuum model approach. Since these constitutional relations themselves are usually determined at the micro- or even nanoscale, they can be understood as a *natural* link between the different scales relevant in materials modelling. In spite of this undeniable impact today's theoretical materials scientists encounter quite often the situation, that *classical* constitutive relations do longer match our precise understanding of a materials microstructure dynamics, since the latter has increased dramatically due to increased experimental accessibility over the last decade. This contribution reviews this situation in terms of mathematical approaches for several phase transition problems in complex materials. Moreover we demonstrate, how homogenization techniques can be employed to derived improved constitutional relations and use them in turn for improved macroscopic continuum model approaches.

Micromechanical interpretation of the quadratic yield function by v. Mises and Hill. **Gerrit Risy** (Universität Magdeburg, Germany), Thomas Böhlke (Universität Karlsruhe, Germany), Albrecht Bertram (Universität Magdeburg, Germany) GA/CT2334/008

Both v. Mises (1928) and Hill (1948) suggested an anisotropic quadratic yield function for a phenomenological description of the plastic behavior of anisotropic solids. Such an elementary approach to the description of mechanical anisotropy has inherent shortcomings. For example, specific experimentally observed distributions of the yield stress and the Lankford coefficient in sheet metals cannot be reproduced by the quadratic yield function.

Nevertheless, the v. Mises-Hill model is currently one of the standard anisotropic plasticity models in the context of a phenomenological setting. Here an overview concerning the properties of the v. Mises-Hill model is given. Furthermore, an interpretation of the fourth-order structure tensor is given in terms of the crystallite orientation distribution function (Böh-

lke, 2005, 2006). Based on this approach the structure tensor can be completely identified by a measurement of the crystallographic texture and of two macroscopic yield stresses.

Mixing modeling for stochastic simulations of turbulent pre-mixed flames. **Michael Stoellinger** (University of Wyoming, USA), Stefan Heinz (University of Wyoming, USA) GA/CT3149/009

Due to the exact treatment of chemical reactions, stochastic methods for turbulent reacting flow simulations have significant advantages compared to deterministic methods. The performance of stochastic methods depends essentially on the modeling of the dynamics of scalar fluctuations (the scalar mixing model). Such models involve two ingredients: changes of scalar values and the characteristic scalar time scale have to be explained. Recent developments did hardly address the latter problem: the scalar time scale is usually assumed to be controlled by the time scale of large-scale turbulent motions (which neglects the influence of chemical reactions on turbulent scalar mixing). This assumption is not justified if the characteristic length scale of scalar fields (reaction zone) is smaller than the Kolmogorov microscale of turbulence. The fact that many turbulent premixed flames of technical interest operate under such conditions leads to the need to develop more general scalar time scale models. A way to overcome this problem by adopting Direct Numerical Simulation (DNS) results will be presented in this talk. The suitability and relevance of this scalar time scale model will be shown in two ways: model predictions will be compared with DNS results and model applications to simulations of several turbulent premixed flames (Aachen flames F1-F3) will be demonstrated.

Statistical modeling of compressible turbulent channel flow. **Stefan Heinz** (University of Wyoming, USA) GA/CT2986/009

Most of the simulations of turbulent reacting flows are performed on the basis of statistical methods because of their relative simplicity. However, the latter fact is the reason for some significant problems, which limit the accuracy of these methods. A first problem is given by the fact that there are good concepts available to model the evolution of velocity and scalar fields, but to close such equations one has to provide the time scale of turbulent motions. Unfortunately, the basis for constructing such a scale-determining equation is weak because the most important term (the source rate) is unknown. A second problem is related to the modeling of wall-bounded flows, which has to be considered in most of the applications. The inclusion of the damping effect of walls is a requirement to perform accurate simulations of such flows. Unfortunately, currently applied concepts for handling this question are either not supported by direct numerical simulation (DNS), or they are not invariant under the Galilean transformation. A third problem concerns the development of solutions for the two problems described above for variable-density flows, which is relevant to turbulent combustion calculations. The relevance and modeling of compressibility effects in wall-bounded flows still represents an open question. Recently obtained DNS results of turbulent supersonic channel flow are analyzed in order to address the three problems pointed out above: the turbulence frequency production mechanism, wall damping effects on turbulence model parameters, and the relevance of compressibility effects. Limited support is found for usually applied models for the turbulence frequency production and wall damping effects. In contrast to that it is shown that turbulence frequency production mechanisms and wall damping effects may be explained very well on the basis of a frequency scaling that characterizes mean flow changes. The influence of compressibility is found to be relevant.

Turbulent boundary layer on a plate with transpiration: dynamical and thermal problems. **Igor Vigdorovich** (Moscow State University, Russian Federation) GA/CT559/009

Closure conditions are derived for turbulent boundary layer flow over a flat plate with transpiration (injection and suction) in the form of universal dependence of turbulent shear stress and heat flux on mean velocity and temperature gradients. The relations can be determined by using but two empirical functions: the velocity and temperature profiles in the turbulent boundary layer flow over an impermeable plate.

As a result, the distributions of velocity, temperature, shear stress, and transverse heat flux in an entire range of parameters and the skin friction and wall heat transfer for the case of arbitrary suction are computed by solving averaged equations under very general physical assumptions without invoking any special closure hypotheses.

Similarity laws for main dynamical and thermal quantities are established as a result of asymptotic analysis of Reynolds-averaged Navier–Stokes and heat transfer equations.

In the case of injection, velocity and temperature everywhere outside the viscous sublayer have universal distributions. For suction, the profiles of these quantities in terms of scaling variables depend on one parameter. The Reynolds tensor components, turbulent heat flux, and rms temperature fluctuation also obey one-parameter scaling laws.

Skin-friction and heat-transfer laws are established such that skin-friction and heat-flux distributions at the wall can be described by universal functions of one variable. The laws are applicable in an entire range of parameters from suction velocities corresponding to an asymptotic suction boundary layer flow to injection velocities giving rise boundary layer blow-off.

Theoretical results are in good agreement with experimental data available.

Dynamic-lift measurements of airfoils. **Gerrit Wolken-Möhlmann** (Carl von Ossietzky Universität Oldenburg, Germany), Joachim Peinke (Carl von Ossietzky Universität Oldenburg, Germany), Stephan Barth (Carl von Ossietzky Universität Oldenburg, Germany) GA/CT4028/009

We present wind tunnel measurements to investigate the dynamic stall effect like it is caused by fluctuations of the wind direction and speed. The lift is determined by the integral of pressure distribution at the wind tunnel walls while rotating the airfoil with defined angular velocity. There is an increase of lift before flow separation on the suction side occurs. The results are discussed on the background of extreme mechanical loads for blades of wind turbines.

A mixing model providing statistics of the conditional scalar dissipation rate. **Daniel Meyer** (ETH Zürich, Switzerland), Patrick Jenny (ETH Zürich, Switzerland) GA/CT1743/009

In the Reynolds-averaged scalar transport equations, the highly non-linear chemical source term can be calculated based on a transport equation for the scalar joint probability density function (PDF). Here, turbulent transport is modeled [R. O. Fox, Computational Models for Turbulent Reacting Flows, 2003]. In velocity-scalar joint PDF methods, turbulent convection is closed. In both approaches, however, molecular mixing needs to be closed by a mixing model. Even though the earliest models were already introduced in the nineteen seventies [P. A. Libby and F. A. Williams, Turbulent Reacting Flows, 1994], mixing models are still an active research area. Here, the challenge is to fulfill the different requirements deduced from the nature of molecular scalar diffusion. We recently introduced a new mixing model [D. W. Meyer and P. Jenny, Physics of Fluids, 18, 2006], which is based on parameterized scalar profiles (PSP). To every particle in the PDF simulation a one-dimensional scalar profile, represented by profile parameters, is attributed. This makes it possible to obtain statistics of spatial scalar derivatives conditioned on the scalar. When treating reacting flows, such data is of great value if laminar flamelets are used [N. Peters, Turbulent Combustion, 2000]. Here, the scalar source term depends on the conditional scalar dissipation rate. In this work, the potential of the PSP mixing model for such turbulent reactive flow computations is investigated.

Turbulent shear-layer scaling in the limit of infinite Reynolds number derived from the unsteady equations of motion. **Bernhard Scheichl** (TU Wien, Austria), Alfred Kluwick (TU Wien, Austria) GA/CT1857/009

By considering the time-mean motion, an asymptotic description of turbulent shear flows in the limit of high Reynolds numbers, conveniently carried out by adopting the method of matched asymptotic expansions, is inherently based on (a few) assumptions regarding the essential physical properties of the flow in the respective tier considered. Although this approach has substantiated some classical results as, for instance, the logarithmic law of the wall, it is, nevertheless, not completely satisfactory from a rational point of view: to this end, we first demonstrate that a rigorous application of the matching principle alone is *not* capable of deducing the aforementioned wall law in the case of boundary layer flows by taking into account the widely accepted presumption of the so-called "inviscid" nature of the fully turbulent main portion of the shear layer. Therefore, to some extent, the usual approaches turn out to be incomplete, for (i) the motivation for the assumptions commonly employed seems not stringent and, unfortunately, (ii) are, stricly speaking, insufficient for developing an asymptotic theory. To be more precise, assumptions which are usually expressed by dimensional considerations can not adequately enter the matching conditions derived from the non-dimensional form of the governing equations, which, however, is required for an asymptotic analysis. Consequently, and as is elucidated, the time-mean scaling of the asymptotic splitting of the flow has to result from an asymptotic analysis of the Navier–Stokes equations by, as the only assumption, considering an asymptotically slender turbulent shear layer. Amongst others, it is shown how a combination of a multiple-scales technique and matched asymptotic expansions leads to the internal splitting of the shear flow (having a large streamwise velocity deficit) that a has already been adopted successfully in former studies regarding its time-mean behaviour, by using rather conventional mixing length arguments.

Active control of combustion instability using fuel-flow modulation. **Daniel Guyot** (TU Berlin, Germany), Christian Paschereit (TU Berlin, Germany) GA/CT3144/009

Modern gas turbine technology relies on lean premixed combustion to satisfy stringent governmental NOx emission restrictions. However, combustion systems operating in the lean premixed mode are highly susceptible to the excitation of high amplitude pressure and heat release fluctuations called thermoacoustic instability. These self-excited oscillations result from the interaction of unsteady heat release in the flame with the combustion chamber's acoustic field and usually lead to increased noise, reduced system performance and reduced system durability.

To minimise this drawback of lean premixed combustion and to ensure safe operation of the combustion system, active instability control can be applied. As described by Rayleigh's Criterion, self-excitation of a combustion system occurs if the fluctuations in heat release from the combustion process are in phase with the pressure fluctuations. Although the real instability processes are somewhat more complex, RayleighŠs Criterion pinpoints how dampening of thermoacoustic instability can be achieved. A common approach is to induce heat release fluctuations, which are out of phase with the pressure fluctuations. Modulated fuel injection is recognized to be an efficient active control method for attenuation of combustion instabilities.

In this work active control is applied to an atmospheric premix combustor test rig equipped with a swirl-stabilized burner by modulating the premix fuel flow. The employed control circuit incorporates condenser microphones recording the pressure oscillations inside the combustion chamber, and valves controlling the fuel mass flow into the combustion system. The microphone signals are processed and command signals are sent to the valves.

The results prove the control circuit's suitability for dampening thermoacoustic instability in a lean premix combustion system. Furthermore, modulation of premix fuel shows significantly lower NOx emissions in comparison to the more common approach of modulated (secondary) pilot fuel injection, as hot spots are avoided.

Generating turbulence using active grids. **Robert Stresing** (Universität Oldenburg, Germany), Joachim Peinke (Carl von Ossietzky Universität Oldenburg, Germany), Pascal Knebel (Carl von Ossietzky Universität Oldenburg, Germany), Mathias Hölzer (Universität Oldenburg, Germany) GA/CT4027/009

Stochastic analysis of turbulent flows generated in a wind tunnel by static grids show a rather large difference compared to the statistical properties found in atmospheric turbulent flows. It is problematic to create large-scale, high intensity turbulence with static grids that shows statistical properties similar to atmospheric turbulence. We present data from an active grid that was installed in the wind tunnel at the University of Oldenburg. The new active grid aims to allow us to generate large-scale homogeneous and quasi-isotropic turbulence. The resulting turbulent flow has a high intensity, a large integral length and shows a distribution similar to atmosperic turbulence.

The interaction of high-temperature heterogeneous jets with construction materials. **Eugene Maslov** (Tomsk Polytechnic University, Russian Federation) GA/CT900/009

High-temperature heterogeneous jets are used for perforation constructional material in power processing, as well as environmental and technical engineering. Analysis via mathematical modeling of this process is important in applied technology engineering. This mathematical model to describe interaction high temperature gases and particles with surface solid and stress–strain condition in mathematical include phase transition. This mathematical model to describe physical process for various values parameters high-temperature heterogeneous jet and physical and thermo-physical properties of material. The problem of accumulation on a still plate of a constructional at concurrence of a normal direction to a streamline surface to an axis of symmetry of a jet heterogeneous subsonic jet of a viscous liquid is solved. Results of the numerical a condition of interaction of solid particles with a surface of a plate are presented. The range of change of parameters of particles and jets at which a surface is established. The typical results of velocity field and temperature distribution which describe basic laws of researching process are represented. The temperature field is compared with experiment data and satisfaction agreement is shown.

Numerische Simulation der Verweilzeitverteilungen in Flotationszellen. **Mario Streng** (Universität Kassel, Germany), Olaf Wünsch (Universität Kassel, Germany) GA/CT2115/009

Verweilzeitverteilungen fluider und fester Partikel dienen zur Charakterisierung mechanischer Trennvorgänge in kontinuierlich durchströmten Apparaten. Die Verteilungen geben Auskunft darüber, wie lange die Partikel im Apparat verweilen. Je nach Prozeß sind breite oder schmale Verteilungsfunktionen erforderlich. Die numerische Simulation solcher Verweilzeitverteilungen auf Basis eines berechneten Strömungsfelds gelingt mit zwei unterschiedlichen Methoden. Zum einen durch die Berechnung vieler Bahnlinien, die den Apparat durchströmen und alle zur gleichen Zeit an verschiedenen Stellen des Eintrittsquerschnitts gestartet sind. Zum anderen über die Einführung einer zusätzlichen Variablen, die als Konzentration verstanden werden kann und deren Ausbreitung im Prozeßraum mittels einer Transportgleichung berechnet wird. Am Beispiel einer Flotationszelle (Rührapparat zur Trennung fester Partikel aus wässrigen Lösungen) werden die Verfahren in Abhängigkeit der Betriebsparameter miteinander verglichen. Der Einfluß der geometrischen Konfiguration von Einlaß und Auslaß auf die Verweilzeitsummenfunktionen wird gezeigt. Sind die Partikel leichter bzw. schwerer als das Fluid, ergeben sich Unterschiede im Vergleich zu masselosen Partikeln. Aus den Ergebnissen lassen sich Hinweise für die Optimierung solcher Prozesse bezüglich der Betriebsparameter entnehmen.

Density of critical points for Gaussian random functions. **Willi Möhring** (Max-Planck-Institut Göttingen, Germany), Horst Vogel (Universität Göttingen, Germany) GA/CT3061/009

Often turbulent phenomena are accompanied by random fluctuations of some scalar quantities. An important property of such salar functions are its critical points,especially their density and type. Letting exceptional cases aside one finds in two- and three-dimesional cases extrema and saddle points. It can be determined from the sign dstribution of the eigenvalues of the Hessian matrix of second derivatives of the function. For two-dimensional functions an easy application of the Poincare-index theorem shows that their densities of saddle points and extrema agree. It does not apply to three-dimensional functions. From Morse-theory one finds that the saddle point density cannot be smaller than the extrema density. Its actual value depends of course on the turbulent field.

Some indications on these quantities can be obtained from random matrix theory. Therefore we consider eigenvalue distributions of Gaussian random matrices. For scalar fields from homogeneous isotropic turbulence the matrices are taken from an orthogonal ensemble. Even if one assumes a Gaussian distribution of the matrices they are not taken from the well known Gaussian orthogonal ensemble (GOE) but from another ensemble which possesses also very interesting properties. For the ratio ρ of the density of saddle points to the density of extrema one obtains then

$$\rho = \frac{1057 + 348\sqrt{6}}{625} = 3.0551.$$

This value is only slightly above three, which would be obtained if one would assume an equidistribution of the eight different sign combinations.

Extended flamelet model and improved interaction of chemistry and turbulence for modeling of partially-premixed combustion with a joint PDF method. **Michael Hegetschweiler** (ETH Zürich, Switzerland), Patrick Jenny (ETH Zürich, Switzerland) GA/CT2987/009

One of the main tasks in turbulent combustion modeling is to accurately describe turbulence reaction interaction. Here, a possible approach how to fulfill this in conjunction with a Joint Probability Density Function (JPDF) approach is shown. For non-premixed turbulent combustion without local extinction the laminar flamelet concept proved to be a good assumption. As a generalization of this approach for partially premixed combustion, an extendend flamelet model considering embedded laminar triple flames is described. From DNS data of e.g. lifted jet flames one knows that embedded edge flames establish at the fine scales. In our modeling approach such laminar triple flames are computed in isolation. At the inflow boundary, the mixture fraction Z varies linearly from zero to one and a constant velocity is applied, such that a steady flame gets stabilized within the domain. At the left and right boundaries, slip boundary conditions with $Z = 0$ and $Z = 1$ are applied. The scalar dissipation rate $\chi \sim 1/L^2$ can be adjusted by varying the width L of the domain. These precomputed tables are then mapped from the 2D physical space to a Z-τ-space, where τ is the residence time of a passive fluid particle in the flame convected along a streamline. In order to use the resulting tables for PDF simulations of turbulent partially premixed flames, mixture fraction $Z^*(t)$, scalar dissipation rate $\chi^*(t)$ and $\tau^*(t)$ have to modeled for each particle. Since reaction occurs only within a relatively small flammable Z-range, this 2D flamelet model is only applied if a particle is located in this range and otherwise a modified IEM mixing model is employed, to compute enthalpy and species mass fraction changes.

Note, that this model accounts for some of the major effects responsible for extinction and reignition in partially premixed turbulent flames.

Modeling of turbulent pre-mixed combustion with a joint PDF method. **Mathias Hack** (ETH Zürich, Switzerland), Patrick Jenny (ETH Zürich, Switzerland) GA/CT2676/009

In many combustion applications the flow field is highly turbulent, and therefore the numerical treatment of the interaction between turbulence and reaction is very crucial. A common model for premixed turbulent combustion is the one by Bray, Moss and Libby (BML). It was developed for simulations in the RANS context and assumes an infinitely thin flame. They introduced a progress variable $c \in \{0, 1\}$ to distinguish between burnt ($c = 1$) and unburnt ($c = 0$) gas. In addition, a transport equation for the Favre average of c, $\tilde{c}$, was derived, in which the turbulent transport and source terms have to be modeled.

Employing the same ideas in combination with a PDF method, where the progress variable c is transported by computational particles, leads to a consistent formulation with the $\tilde{c}$-equation in the BML approach. It is an advantage, however, that in the PDF equation the turbulent transport of c appears in closed form. Moreover, by introducing the burning time τ, the embedded quasi laminar 1D flame profile can be resolved. This is achieved by measuring the τ for each computational particle (the time since the particle's c-value switched from zero to one). Assuming that the flame front propagates with a known velocity s_L relative to the particle position, the evolution of the composition, including enthalpy, can be determined from precomputed tables, provided τ is known. The main challenge, which has to be addressed in this context, is to estimate the ignition probability (when does c switch from zero to one?). The modeling approach and possible closures for the source term are discussed and examined with numerical experiments.

Flame propagation in free vortices. **Hannes Kröger** (Universität Rostock, Germany), Nikolai Kornev (Universität Rostock, Germany), Egon Hassel (Universität Rostock, Germany), Detlef Wendig (Universität Rostock, Germany) GA/CT2293/009

Object of this paper are experimental and numerical investigations of the Combustion Induced Vortex Breakdown (CIVB) phenomenon in a free straight vortex. The experiments were performed using a swirl generation device. A swirling jet of premixed methane/air is ejected by this device into the ambient surrounding air. At some distance above the swirler nozzle, there is a ring burner mounted which holds a stationary flame. When conditions for a flashback are met, i.e. the swirl number exceeds S=0.25 at a equivalence ratio of ϕ=0.7, the flame of the ring burner propagates against the main flow back to the nozzle.

The isothermal flowfield has been studied experimentally under the flashback conditions (S=0.25) using Laser Doppler Velocimetry (LDV) and Particle Image Velocimetry (PIV). It follows from the measurements, that there is no vortex breakdown in the isothermal flow. Furthermore, the axial velocity in the isothermal flow exceed the turbulent burning velocity everywhere by a factor of at least two. Nevertheless, in the reacting flow with the same flow parameters, a flashback occurs. The flashback event was documented using high speed camera films.

To confirm experimental observations and gain more insight into the phenomenon, numerical simulations of the flashback event were performed using the open source finite volume code OpenFOAM. To model the influence of turbulence, the large-eddy simulation technique was applied. For combustion modelling, a flame surface wrinkling model was used.

LES simulations clearly show the appearance of a small area of negative axial velocities in front of the flame tip. This is a remarkable feature indicating the presence of the CIVB. Analysis of the LES data points out that the flame propagation against the main flow occurs mostly by induction effects caused by the circumferential vorticity appearing due to the radial expansion of the vortex tube. The expansion causes a strain field spiraling the vorticity field. On the contrary, the vorticity appearing due to the volume expansion caused by the combustion counteracts the flame flashback. The baroclinic effect promotes the flame propagation. However, its effect is small.

Mechanism of fire-tornado formation. **Yuri Rudi** (Tomsk State University, Russian Federation), Anatoly Grishin (Tomsk State University, Russian Federation) GA/CT903/009

Fire tornadoes refer to the kind of atmospheric tornados. As a rule, they are caused by the matt urban or forest fires. Mechanism of occurring and evolution in the tornado is impossible to investigate under the natural conditions. Therefore investigating a mechanism of the fire tornado formation is very important. Fire tornadoes were imitated under the laboratory conditions by means of three experimental set-ups based on twisting the ascending convective flow of the oil combustion products (modeling fires at the oil reservoirs), wooden constructions (modeling fires in the populated areas) and forest fuels (modeling forest fires). Convective flow was twisted by rotating the lower base of the substrate with forest fuels, rotating at the top fans of the ventilator and at the side by means of an air flow generated by aerodynamic pipe. All the fuels were placed on the special substrates. Then they were ignited. A diameter of the substrates in different tests amounted to (6, 7, 10, 12, 20)e-2 m, while the height was (2, 6, 12)e-2 m. The diameter of the substrates coincided with that of the combustion area. It is shown, that fire tornado formation does not depend on the method of their generation and the kinds of the forest fuels, but it is determined by the values of the density of the heat flow caused by combustion and by an angular velocity (frequency) of the cylinder rotation w=(1,1-1,3) Hz, in which the forest fuel is placed. When w />/ 1,3 Hz, the fire tornado was unstable and decomposed. Stable tornado occurs at the definite (critical) velocity of rotation, determined by equilibrium of the forces acting on the flame: providing a moment of twisting a vortex. The time of the stable combustion is 18-20 seconds. It was established, that in the flow twisted from the bottom the time of combustion was 10 percent less than without the flow twisting. It is explained by increasing the velocity of diffusion combustion at the expense of hydrogen supply from the environment, since in a radial direction an air from the environment arrives to column-shaped tornado, while a combustion regime in the tornado is diffusive. Hydrodynamic criteria of similarity of the problem to be solved Gr, Pr, Fr, Os have been estimated. Criterion dependencies between them have been found.

Interactions between compressibility and heat release in turbulent mixing layers. **Inga Mahle** (TU München, Germany), Rainer Friedrich (TU München, Germany) GA/CT994/009

When the convective Mach number increases, there is a large reduction in the thickness growth rate and the turbulent intensities of a mixing layer which has important implications for applications such as scramjet engines. Additionally, the damping effect of heat release due to combustion adds to the already stablizing effect of compressibility. Since perfect mixing of oxidizer and fuel is a pre-requisite for complete combustion, it is of particular interest to understand the mechanisms that play a role when compressibility and heat release interact.

With this aim, highly resolved DNS of inert and reacting temporally evolving mixing layers at different convective Mach numbers ($M_c = 0.15$, 0.7 and 1.1) are performed. All computations achieve a self-similar state with Reynolds numbers based on the instantaneous vorticity thickness between 10000 and 20000.

The present results show that besides a decrease of the production term in the balance equation of the streamwise Reynolds stress, the pressure-strain correlation in this equation is also reduced by both, compressibility and heat release. It can be shown that this is a consequence of the alterations

in the fluctuating pressure fields. Therefore, an investigation of the pressure fluctations leads to a further understanding of their changes by compressibility and heat release.

GA/PP896/009: **On aerodynamical optimization of wind-farm layout by genetic algorithm method.**

Presenter: Bosko Rasuo (University of Belgrade, Yugoslavia)
Co-author: Aleksandar Bengin (University of Belgrade, Yugoslavia)
Co-author: Aleksandar Veg (University of Belgrade, Yugoslavia)

This paper presents a method for determination of optimum positions of single wind turbines within the wind farms installed on arbitrary configured terrains, in order to achieve their maximum production effectiveness. This method is based on use of the genetic algorithm as optimization technique. The wind turbine aerodynamic calculation is unsteady, based on the blade modeled as a vortex lattice and a free-wake type airflow behind the blade. Optimization method is developed for two different fitness functions. Both functions use the total energy obtained from the farm as one of the key variables. The second also involves the total investments in a single wind turbine, so the optimization process can also include the total number of turbines as an additional variable. The method has been tested on several different terrain configurations, with special attention paid to the overall algorithm performance improvements by selecting certain genetic algorithm parameters.

GA/MP29/010: Dynamics of transitional separation bubbles.

Organiser: Ulrich Rist (Universität Stuttgart, Germany)
Co-organiser: Stefan Braun (TU Wien, Austria)

Adverse pressure gradient laminar boundary layers at low to medium Reynolds numbers are strongly susceptible to separation. Due to the deceleration of the main flow the laminar boundary layer separates from the solid surface and typically undergoes fast laminar-turbulent transition which is followed by reattachment of the shear layer being already turbulent. The area of recirculating flow causing negative skin friction is called a *laminar separation bubble* (LSB) or alternatively a *transitional separation bubble*.

In general LSBs are known to affect the overall flow properties only minor but react very sensitively to external disturbances such as free-stream turbulence, impinging sound waves, structure vibrations etc., which may result in the *bursting* of the (short) bubble leading either to a more pronounced separated flow region or even global separation. Both cases are accompanied by sudden and often unwanted major changes of aerodynamic forces; e.g., loss of lift and increase of drag. It is mainly this fact which explains the undiminishing research interest in this phenomenon for more than seventy years which can be found in various applications: low Reynolds number aerodynamics, unmanned aerial vehicles, on the wings of man-carrying gliders, vanes of turbo-machines, blades of wind-energy converters, and even on the slats of large commercial jet-powered airliners.

Because of the complicated spatio-temporal flow structure of transitional separation bubbles the underlying flow physics is still not well understood. The idea of the present mini symposium is to give both an overview and a detailed look into particular problems associated with the emergence of LSBs, the transition process and its interference. Experts will present their most recent achievements in this attractive field of research using different approaches: stability theory, boundary layer asymptotics, direct numerical simulations, hot-wire measurements and particle-image velocimetry.

Experiments on control of laminar separation bubbles through passive and active techniques. **Alexander Dovgal** (Kristianovich Institute, Russian Federation), Victor Kozlov (Kristianovich Institute, Russian Federation) GA/MT439/010

Recent experimental data obtained in ITAM SB RAS on control of laminar separation bubbles at low subsonic velocities are summarized. In a low-turbulence wind tunnel, both passive and active control methods aimed at optimization of mean and oscillatory separated flow characteristics were examined. The methods employ stationary local and periodic modulations of a body surface, generation of acoustic waves, oscillatory and continuous suction of the near-wall fluid. A number of beneficial control effects have been observed through application of the above techniques. It is found that a promising way to improve operation of airfoils is utilization of a wavy lifting surface. In particular, modification of the separated flow pattern produced by the spanwise waviness of the wall prevents from global flow separation at high angles of attack increasing the critical incidence of airfoil. Also, the wind-tunnel data give indications of a strong response of separated flows on finite-span wings to 3D local stationary perturbations of the surface rearranging the entire flow pattern. Periodic forcing and suction applied to a back-step flow were found as effectively controlling the separated flow unsteadiness dominated by the large scale vortices shedding from the separation bubble. Thus, the energetic low frequency motion induced by separation bubbles can be suppressed. The above observations are discussed emphasizing fundamentals of the control approaches relevant to instability of laminar separating boundary layers.

3D vortical structures of a laminar separation bubble on an SD7003 airfoil. **Wolfgang Schroeder** (RWTH Aachen, Germany), Sebastian Burgmann (RWTH Aachen, Germany) GA/MT2346/010

The laminar separation bubble on the suction side of an SD7003 airfoil has been investigated using the Scanning Particle-Image Velocimetry (SPIV) technique. Due to an adverse pressure gradient the laminar boundary layer detaches at $Re_c < 100.000$. Transition occurs and leads to a turbulent reattachment of the separated shear layer enclosing a recirculation region. Kelvin-Helmholtz instabilities force the shear layer to roll up in the reattachment region such that vortices occur that separate from the main recirculation region and propagate downstream.
Using the Scanning PIV technique these vortical structures in the reattachment region can be analyzed in detail concerning the three-dimensional structure and their time-dependant development. For using the PIV technique the flow has to be seeded with small tracer particles. In an illuminated measurement plane the scattered light of the particles is detected with a camera. Recording the flow at least twice leads to particle images with a movement of the particles from picture 1 to 2. This particle movement can be converted into a velocity field using cross-correlation routines. The Scanning PIV technique uses a moving light-sheet to illuminate distinct planes within the measurement volume to investigate the flow field within a volume instead within a single plane. The separated flow of a SD7003 airfoil has been investigated at a Reynolds number of 20.000 and at angles of attack of $4°$ to $8°$. The size and position of the separation bubble has been analyzed as well as the flapping-frequency of the vortical structures that evolve in the reattachment region. Using a stereo set-up all three velocity components have been detected in each light-sheet plane leading to a quasi-three dimensional measurement of the reattachment region. Typical vortical structures like the c-shape vortex and the screwdriver vortex have been detected and their spatio-temporal development has been visualized.

3D effects on swept laminar separation bubbles. **Tilman Hetsch** (University of Southampton, UK), Ulrich Rist (Universität Stuttgart, Germany) GA/MT1418/010

Direct numerical simulation (DNS) is used as a tool to investigate different aspects of the influence of sweep on a series of pressure-induced laminar separation bubbles. So far research efforts have been nearly exclusively concentrated on unswept case. But in important technical applications, as on high lift devices of modern airliners, laminar separation bubbles appear naturally in swept geometries. Therefore, the talk concentrates on three phenomena connected with a swept inflow: 1. The effect of sweep on the undisturbed base flow itself. Based on the independence principle and backed by an experiment it can be shown that there is an universal topology of swept laminar separation bubbles in the geometry of an infinite swept wing. 2. The effect of different propagation directions of the primary disturbance in fundamental transition scenarios on the onset of transition. It turns out that two-dimensional Tollmien-Schlichting waves, which are so important in the unswept case, quickly loose their dominance to oblique TS-waves as the sweep angle increases. 3. The growing influence of cross-flow instabilities with rising sweep angle. The interaction of high-amplitude stationary crossflow vortices on the fundamental transition scenarios investigated before is studied for the high sweep angle of 45 degrees.

Mean flow deformation in a laminar separation bubble. **Olaf Marxen** (Stanford University, USA), Ulrich Rist (Universität Stuttgart, Germany) GA/MT887/010

An important effect occurring during laminar-turbulent transition in a pressure-induced laminar separation bubble on a flat plate is investigated by means of Direct Numerical Simulations. Such a separation bubble can originate if a boundary layer is subject to a sufficiently-strong adverse pressure gradient. Transition occurs in the detached shear-layer, which in most cases results in mean reattachment, thus forming a closed bubble in the mean.

The investigation of the effect of mean flow deformation (MFD) is devoted to the upstream; i.e., feedback, effect on the flow in the mean, caused by a small, unsteady disturbance input that provokes transition. With such a disturbance, the resulting viscous-inviscid interaction evokes a large mean flow deformation; i.e., a change of the flow field in the mean, that reaches far upstream. While the MFD at transition is caused directly via the non-linearity of the Navier–Stokes equations, the mean flow deformation upstream is induced indirectly via a change in the streamwise pressure distribution caused by the saturated disturbances. It is shown that the effect of this mean flow deformation in the potential-flow region further away from the wall can be modeled using a source/sink distribution at the wall.

Two different central effects are observed that are caused by the small disturbance input: a reduction of the size of the separation region (i.e., a smaller separation bubble in the mean); and a stabilization of the flow with respect to small, linear perturbations upstream (i.e., in the laminar part). Aided by the application of linear stability theory it is shown that studies of linear perturbations in disturbance formulation are meaningful if based on the deformed, time-averaged flow field only; i.e., for a known transition process.

Transitional separation bubbles on airfoils. **Neil Sandham** (University of Southampton, UK), Lloyd Jones (University of Southampton, UK) GA/MT2700/010

An unsteady viscous-inviscid interaction method is tested against recent results from direct numerical simulation and experiment. The unsteady method is a time-accurate extension of traditional methods of coupling integral boundary-layer methods with a potential flow solution based on panel methods. The unsteady formulation, including an envelope-based transition model is shown to be capable of predicting large-amplitude low-Strouhal number oscillations as seen in several recent experiments. Above a critical incidence the airfoil separation bubble reattachment point can no longer be held and the flow develops a limit cycle behaviour in which the bubble growth leads to fully stalled flow followed by a reformation of the bubble. The mechanism depends on strong coupling between the potential flow and the boundary layer. The unsteady model is also calibrated against results from recent direct numerical simulations of separation bubbles on NACA-0012 airfoils. At low incidences the airfoils exhibit short separation bubbles with convective growth of instabilities. At higher incidence we investigate the simulation and modelling of airfoils with localized regions of absolute instability.

DNS of laminar separation bubble flows with free-stream fluctuations. **Jan Wissink** (Universität Karlsruhe, Germany), Wolfgang Rodi (Universität Karlsruhe, Germany) GA/MT1302/010

In the presence of a strong enough adverse pressure gradient, a laminar boundary layer over a flat plate will separate. The separated boundary layer (shear layer) is very unstable and will usually undergo rapid transition to turbulence. Experiments showed that the presence of external fluctuations can drastically reduce the size of a Laminar Separation Bubble (LSB). To elucidate the physical mechanisms involved, a series of Direct Numerical Simulations (DNS) of separating boundary-layer flows over a flat plate were performed.

In accordance with the companion experiments performed at the Technical University of Berlin, in the DNS the adverse pressure gradient was induced by a contoured upper wall. In the spanwise direction of the computational domain periodic boundary conditions were employed, while at the outlet a convective outflow condition was prescribed. The Reynolds number of the flow problem, based on the local free-stream velocity and the momentum loss thickness, θ, of the boundary layer just before separation was approximately $\mathrm{Re}_\theta = 90$.

The influence of two types of free-stream fluctuations, both superposed on a uniform inflow, on the dynamics of the LSB were considered:

1. A streamwise oscillation of which both the amplitude and the period were varied
2. Grid *turbulence* of which the level was varied

In all simulations, the primary mechanism for the transition to turbulence was found to be a two-dimensional Kelvin–Helmholtz (KH) instability of the separated shear layer that was triggered by the external fluctuation(s). The KH instability caused the shear layer to roll up. Inside the rolled up shear layer, entrained disturbances triggered elliptic instabilities which led to a rapid transition to fully three-dimensional (3D) turbulence.

Global stability calculations of separated flows. **Jitesh Gajjar** (University of Manchester, UK) GA/MT1562/010

The primary motivation for the current work is to develop suitable techniques for studying the global instability in many different flows such as that occuring in the flow past a row of circular cylinders placed in a uniform stream, see Gajjar & Azzam (2005), or in the supersonic flow past a compression ramp, Fletcher et.al. (2004). In the latter problem, for sufficiently large ramp angles, the flow in the recirculation region near the corner becomes unstable and it was suggested in Fletcher et.al. (2004) that an absolute instability may be responsible for the abrupt local breakdown of the bounday layer. In both these quite different problems a common difficulty is the generation of the mean steady flow which is needed for input into an eigenvalue solver. For the flow past a circular cylinder, the accurate computation of the steady flow is difficult, as the work of Gajjar & Azzam (2005) and Fornberg (1991) has demonstrated. The precise manner in which the equations and boundary conditions are handled, and the accuracy of the numerical techniques used is very important, and crude techniques do not work well. In the supersonic corner ramp problem, the computations of the steady flow encounter severe difficulty especially for large corner angles when secondary separation is present, see Korolev et. al. (2002). Here, even with

sophisticated numerical methods, large-scale separation poses considerable problems.

In the current work we have extended the methods used to compute the steady flow past a cascade of circular cylinders, and the supersonic flow past a compression ramp, to study the global instability of these flows. In this talk we will discuss the methodology and the results obtained.

Convective and global instabilities in separated flows. **Jean-Christophe Robinet** (École Nationale Supérieure d'Arts et Métiers, France) GA/MT1103/010

The following paper is devoted to laminar separated boundary-layer flows of incompressible fluids. Laminar boundary-layer separation is a fondamental phenomenon and has a number of related applications. Low Reynolds number aerodynamics of airfoils, flow over steps, humps and other kinds of localized variations of a surface are striking examples of aerodynamical problem which concern laminar separation. Thus, laminar separated flows have been addressed for decades and significant success has been achieved in experimental, numerical and theoretical studies.

A feature of laminar separated flows is that they become unstable even at relatively low Reynolds numbers. As a result, such flows usually involve unsteadiness and a transition to turbulence. In the most of cases, when considering the evolution of oscillations in a separated flow, the primary instability is assumed to be convective. Nevertheless, an absolute instability can occur in the strong back-flow regimes (Rist & Maucher, 2002).

More recently Theofilis *et al.* (2000) have shown that there is a three-dimensional and stationary instability wave family not envisaged by the weakly non-parallel theories being able to play an important part in the transition mechanisms. However,this study does not consider the case where there are at the same time convectives instabilities coming from the upstream of the flow and an intrinsic global instability in the separated zone. The objective of this paper is to show that a global stability approach of a laminar separated flow permits to study the case where the flow is at the same time convectively unstable at upstream and downstream to the separated zone and globally unstable in separated zone. Two families of modes will be shown: spatially convective global modes and non convective global modes.

GA/MP29/010: Dynamics of transitional separation bubbles. #3

Organiser: Ulrich Rist (Universität Stuttgart, Germany)

(For abstract, see session #1 above.)

Laminar separation bubbles from a high Reynolds-number asymptotic point of view. **Stefan Braun** (TU Wien, Austria) GA/MT1943/010

Classical boundary layer theory proved to lose its validity if flow separation is encountered. However, introduction of the triple deck concept – i.e. allowing for the displacement effect of the viscous boundary layer to interact locally with the induced pressure (disturbances) in the outer inviscid flow regime – led to a successful description of 'short' laminar separation bubbles in various fundamental flow problems. Here we want to focus on situations which share the following distinctive feature: two-dimensional steady state solutions of the underlying interaction equations exist in a limited range of values of a parameter controlling the conditions leading to separation only. Furthermore, these solutions turn out to be non-unique in the vicinity of the limiting *critical* value of this parameter. Typical examples include leading edge separation, smooth backward facing step flow, channel flow with suction, subsonic expansion ramp flow, asymmetric trailing edge separation etc. More recent investigations which take into account (local) unsteady, three-dimensional and flow control device effects and concentrate on *near critical* flows indicate that *(i)* exceeding the critical value of the controlling parameter is associated with self-sustained vortex shedding (time periodic bubble 'bursting' even in the absence of external disturbances), *(ii)* coherent structure formation caused by bubble bursting events turns out to be essentially self-similar, *(iii)* the high sensitivity of the separated flow region with respect to external disturbances allows for effective application of (optimized) flow control devices in order to force or delay the transition process to turbulent boundary layer flow. The aim of the presentation is to deliver insight into the achievements of modern asymptotic analysis in the topic under consideration.

On viscous–inviscid interaction in transonic flows. **Anatoly Ruban** (University of Manchester, UK) GA/MT2211/010

This paper is concerned with theoretical analysis of the behaviour of the transonic flow past a convex corner on a rigid body surface. It is known from experiment that the flow can take two forms, with separation from the corner and attached form of the flow. The latter undergoes fast acceleration from subsonic speed before the corner to supersonic Prandtl-Meyer flow behind the corner.

Assuming the Reynolds number large, we starts with the inviscid part of the flow, where the solution of the Kármán-Guderley equation may be constructed analytically using the hodograph method. This gives the pressure distribution for the boundary layer that forms on the body surface. The pressure gradient appears to be different for the separated and attached flow regimes. However, in both cases a singularity develops on approach to the corner; for the separated flow $dp/dx \sim (-x)^{-1/3}$, while for the attached flow $dp/dx \sim (-x)^{-3/5}$. Here p denote the pressure and x the distance from the corner apex.

The solution for the boundary layer also develops a singularity. It splits up into two parts, viscous near-wall sublayer and locally inviscid main part of the boundary layer. We found that contrary to what happens in subsonic and supersonic flows, the contribution of the main part of the boundary layer contributes into the displacement effect is no longer negligible. In fact, for the separated flow regime it dominates the contribution of the viscous sublayer. For the attached flow, the two parts of the boundary layer contribute equally. However, in this case, an intermediate layer forms between viscous and inviscid parts of the boundary, and this is the intermediate layer that defines the displacement effect of the boundary layer as a whole.

The presentation will be concluded with the discussion of the solutions for the viscous-inviscid interaction region that forms near the corner.

Receptivity of the boundary layer with separation bubble to external sound waves. **Vladimir Zametaev** (Central Aerohydrodynamic Institute, Russian Federation), Marina Kravtsova (Central Aerohydrodynamic Institute, Russian Federation) GA/MT2309/010

The receptivity problem of laminar separated two-dimensional boundary-layer under influence of external acoustic waves is considered. Basic features of this theory were formulated by Ruban (1984) and Goldstein (1985), but these investigations were limited by small perturbations of steady parallel flow only. This paper is concerned with essentially nonparallel regimes of base flow, including attached flows, flow with separated bubbles and base flow at marginal value of the main parameter. The steady flow near a corner point of profile is of considerable interest and a question naturally arises about the sensitivity of separation bubble inside the BL to external disturbances such as sound waves. Another question arises about the sensitivity of near critical base flow, namely if corner is convex there is a marginal angle which limits existence of such base interaction flow. This fact usually is linked with a sudden reconstruction of full flow pattern past a profile. Development of perturbations inside the interaction region may give some answers on the T-S waves development and appearance of turbulence. The asymptotic problem includes two set of equations. The first boundary-layer problem describes the separation flow near a corner point of a rigid body contour. The steady solution is calculated using an effective numerical method. Second unsteady interaction problem describes development of periodical in time perturbations incoming from upstream. Calculations were made for different regimes including attached and separated flows. First of all for zero displacement to study development and viscous decreasing of perturbations for different values of the frequency of sound wave ω and then taking into account interaction process. It is of interest that perturbation which achieves zone of separation has fast periodical behavior with large amplitude. Full problem calculations were made and results describe sharp development of perturbation along the interaction region. /enddocument

Dynamical flow phenomena associated with the laminar separation bubble on an SD7003 airfoil. **Christian Kaehler** (TU Braunschweig, Germany), Rainer Hain (TU Braunschweig, Germany) IC/MT4439/010

In the past, many numerical and experimental investigations on Laminar Separation Bubbles (LSB) have been performed, see Lang et al. (2001) and Radespiel et al. (2006) for instance. One reason is that these bubbles can have a strong influence on the flow around an airfoil so that both the lift and the drag are affected. The LSB's mainly occur at thin airfoils at Reynolds numbers $Re = 5 \times 10^4$ - 5×10^5. Many of the investigations of LSB's were done for generic test cases or by means of measurement techniques which do not allow capturing the flow phenomena with a high spatial and temporal resolution (e.g. LDA or conventional PIV). Ol et al. (2005) summarizes a comparison between investigations on the SD7003 airfoil at Re = 60000 and an angle of attack of 4° in different test facilities. The measurements were done by means of conventional PIV to determine statistical quantities such as the size and shape of the bubble, the onset of turbulence in the shear layer and the point of were the turbulent reattachment takes place.

To understand the complex 3D flow topology of the laminar separation bubble with the transition and vortex shedding process, the temporal evolution of the flow structures was investigated by Hain et al. (2005) with different time resolved PIV techniques. Beside the 3D topology the dominant frequencies of the transition process and the vortex shedding were determined. In order to investigate the dynamic processes in further detail, scanning PIV measurements have been performed on a SD7003 airfoil at a Reynolds number of Re = 60000.

Different light sheet orientations were realized in order to analyse the three-dimensional dynamic of the shed vortices. In the configuration with the light sheet parallel to the airfoil surface, the interaction between the vortices can clearly be seen. The light sheet orientation normal to the airfoil in main flow direction allows a detailed analysis of the transition process. Based on these experiments a detailed understanding of the dynamical processes could be established as will be outlined at the conference.Lang M, Marxen O, Rist U, Wagner S: Experimental and numerical investigations on transition in a laminar separation bubble. GA/MP142/010: Influence of the geometry of the boundary on flows in layers.

Organiser: Markus Scholle (Universität Bayreuth, Germany)
Co-organiser: Hannes Uecker (Universität Stuttgart, Germany)

Fluid layers frequently occur in nature as well as in technology. Rain wetted roads or the tear film of the eye are examples for films encountered in environmental or biological systems. In industries, we find fluid layers in coating applications and lubrication problems. In the past, much attention was paid to the stability of plane films, whereas in recent times the influence of the wall topography due to e.g. steps, trenches or periodic corrugations on the flow has become subject of detailed investigations, increasingly. These investigations deliver creation of kinematically induced eddies in creeping flows, a shift of the stability limit in flows at moderate Reynolds numbers and pattern formation like hydraulic jumps and nonlinear resonance effects at higher Reynolds numbers. Consequences for material and heat transport induced by eddies are also subject of this minisymposium.

Stationary solutions and linear stability for film flow over wavy bottoms for large Reynolds numbers. **Tobias Häcker** (Universität Stuttgart, Germany) GA/MT4468/010

We study the flow of an incompressible liquid down an incline with a periodically undulated bottom. In the case of high Reynolds numbers we derive an Integral Boundary Layer equation as a thin film approximation. This has spatially steady solutions which can be expanded in terms of the dimensionless film thickness. With a linear stability analysis based on Bloch wave transformation we show the existence of a critical Reynolds number corresponding to the results over flat inclines.

Inertial effects in film flow along strongly deformed walls: deep periodic corrugations and abrupt steps. **Vasilis Bontozoglou** (University of Thessaly, Greece) GA/MT558/010

Liquid film flows are of central importance in many industrial processes. The wall on which the film moves is frequently irregular, either intensionally as in process intensification or accidentally as in the coating of defective surfaces. This talk presents recent computational findings on the free surface configurations and flow structures attained along strongly deformed walls.

A periodically corrugated wall is known to resonate with the liquid film, resulting in a steady flow with strongly deformed free surface. Deep corrugations eventually lead to steady separation, whose extent at $\mathrm{Re} = O(10)$ depends non-monotonically on film thickness. For thick films the separation region tends asymptotically to cover half of the corrugation trough and the resulting flow structure has similarities with creeping flow. For progressively thinner films, the separation region initially shrinks (or even disappears) but then grows impressively to cover most of the corrugation trough. The latter behavior is attributed to the combined effect of the strong wall and free surface deformations, whose phase difference induces a pinching of the film that triggers inertial separation.

Isolated orthogonal steps along an otherwise flat wall induce local deformations (ridges, depressions) on the upstream side of the free surface, which provide the capillary pressure needed to change the flow direction. The characteristic length of these deformations is predicted from simple scaling arguments, and the transition from a capillary-gravity to a capillary-inertia regime is identified. With increasing Re, the upstream deformations initially intensify but subsequently receed and disappear. This change is understood as a result of increasing flow separation, which smoothens the directional variations induced by topography. At higher Re, purely inertial deformations appear, which are produced by liquid overshoot at the exit of the step. Here, capillarity is resisting deformation, and thus the dependence on surface tension is reversed.

Resonance in viscous film flow over topography. **Andreas Wierschem** (TU München, Germany), Vasilis Bontozoglou (University of Thessaly, Greece), Christian Heining (Universität Bayreuth, Germany), Nuri Aksel (Universität Bayreuth, Germany) GA/MT1159/010

We study viscous gravity-driven films flowing over periodically undulated substrates numerically, analytically, and experimentally. Linear analysis describes resonance in steady flow along small amplitude corrugations for films of arbitrary thickness. Depending on the dimensionless film thickness we find different regimes for the resonance, which is associated with the interaction of the undulated film with capillary-gravity waves traveling against the flow. Nonlinear resonance produces higher harmonics and bistable resonance. The higher harmonics are due to higher-harmonics resonance and due to the nonlinear coupling to lower harmonics. For the bistable resonance we derive a minimum model showing that the bistability corresponds essentially to that of the driven Duffing oscillator.

Nonlinear stability for film flow over wavy bottom. **Hannes Uecker** (Universität Stuttgart, Germany) GA/MT1082/010

We consider a spatially periodic Kuramoto–Sivashinsky equation as a model problem for inclined film flow over wavy bottoms and other spatially periodic systems with a long wave instability. We show that linearly stable stationary solutions are also nonlinearly stable, and that perturbations decay in a characteristic self similar way determined by a Burgers equation in Bloch wave space, which is the amplitude equation of the problem.

The analysis is based on Bloch wave transform and renormalization group methods.

GA/MP142/010: Influence of the geometry of the boundary on flows in layers. #2

Numerical simulation for the flow of continuous thin liquid films over topography. **Harvey Thompson** (University of Leeds, UK), Philip Gaskell (University of Leeds, UK), Yeaw Chu Lee (University of Leeds, UK), Markus Scholle (Universität Bayreuth, Germany), Nuri Aksel (Universität Bayreuth, Germany) GA/MT1111/010

Free surface full film flows over topography are of great scientific interest and play a vital role in several important biological, engineering and manufacturing processes. However, the unravelling of such flows presents a considerable challenge to experimentalists and theoreticians alike; the investigation of the effects of localised topography being particularly demanding. Accordingly, this paper considers the present state-of-the-art associated with the accurate numerical solution of such problems for a range of three-dimensional flows.

The benefits of employing a lubrication framework to derive a tractable set of governing equations for Stokes' flow, with their resulting Finite Volume analogues solved optimally using an implicit multigrid scheme, is demonstrated. Reported also are the benefits to be accrued from implementing automatic error-balanced mesh adaptivity and time integration without loss of accuracy.

Solutions to a number of three-dimensional gravity-driven flow problems are presented, which include: (i) continuous thin film flows over single and grouped topography; (ii) the effects of evaporation for the same; (iii) the presence of occlusions (blockages) in regions of the flow domain; (iv) minimisation of free-surface disturbances.

Finally, from the point of view of establishing the appropriateness or otherwise of pushing the bounds of the lubrication approximation to solve the above problems, the importance of inertia is quantified by comparing solutions obtained for the simpler case of flow over two-dimensional topography; with corresponding results obtained using a finite element discretisation of the associated Navier-Stokes equations

Influence of eddies on heat transfer in Couette flow over undulated substrates. **Markus Scholle** (Universität Bayreuth, Germany), Harvey Thompson (University of Leeds, UK), Nuri Aksel (Universität Bayreuth, Germany), Philip Gaskell (University of Leeds, UK) GA/MT1036/010

In Couette flows over undulated substrates eddies can be generated under creeping flow conditions. In contrast to free surface flows on undulated substrates even smooth bottom undulations allow for eddy generation due to the kinematical constraints. The subject of our paper is how these flow patterns interact with the temperature field in non-isothermal flows.

We consider the steady Couette flow of a Newtonian fluid between two plates, one of them planar, the other one with a sinusoidal profile. Additionally, a transversal heat flux is imposed by a temperature difference between the two plates. Our analysis of the thermo-mechanical coupling is focused on the two dominant effects, namely convection and thermoviscosity, whereas dissipation heat, buoyancy and temperature-dependence of the remaining material parameters are neglected.

We solve the problem in two steps: First, the influence of the eddies on the convective heat transfer is considered by solving the heat conduction equation with convection. For the velocity field we take the solution resulting analytically from Reynolds' lubrication approximation for the isothermal flow. Second, the thermoviscous feedback of the resulting temperature field to the flow is taken into account.

For the construction of the solution an analytical approach based on a non–orthogonal series representation of the fundamental fields and a variational formulation of the field equations is used. The results are visualised and the physical effects they reveal are discussed.

Numerische Strömungssimulation viskoelastischer Fluide . **Olaf Wünsch** (Universität Kassel, Germany), Mathias Krebs (Universität Kassel, Germany) GA/CT2162/010

Bei der Simulation von Strömungen von Flüssigkeiten mit Gedächtnis müssen die aktuellen Reibungsspannungen aus der Geschichte der relativen Deformationen berechnet werden. Dies kann einerseits mit integralen Materialmodellen erfolgen, erfordert aber die Verfolgung der Fluidelemente auf ihren Bahnen in die Vergangenheit und die Integration der dabei erlebten Deformationen. Dagegen werden bei den differentiellen Modellen nur die Spannungen und Deformationen zur aktuellen Zeit benötigt, allerdings auch deren zeitliche Ableitungen. Letztere Modelle führen bei der Strömungsberechnung auf zusätzliche Differentialgleichungen für die Spannungskomponenten, die simultan mit den Bewegungsgleichungen und der Kontinuitätsgleichung gelöst werden müssen. In diesem Vortrag geht es um numerische Berechnungen von Strömungen mit differentiellen Stoffmodellen unter Verwendung eines finiten Volumenverfahrens. Die zusätzlichen Spannungsdifferentialgleichungen lassen sich in Form von Transportgleichungen in das Verfahren integrieren. Beim Lösen der Gleichungen muss auf deren speziellen numerischen Eigenschaften Rücksicht genommen werden. Verschiedene Materialmodelle (Oldroyd, Giesekus, Tanner) kommen zum Einsatz, deren Eignung zur Beschreibung realer, hochviskoser Füssigkeiten diskutiert werden. An Hand von Strömungsimulationen in zweidimensionalen Geometrien wird die Vorgehensweise bei der Berechnung gezeigt. Die Ergebnisse werden mit analytischen Berechnungen und Literaturdaten verglichen. Schließlich erfolgt die Anwendung des Verfahrens auf Strömungen in realen, dreidimensionalen Geometrien. Bei der Umströmung von Partikeln und der Durchströmung von Apparaten der Verfahrenstechnik sind deutliche Einflüsse der Viskoelastizität zu erkennen.

Simulation der anisothermen Strömung in einem Doppelschneckenextruder. **Carsten Conzen** (Universität Kassel, Germany), Olaf Wünsch (Universität Kassel, Germany) GA/CT2118/010

Doppelschneckenextruder werden im Maschinenbau und in der Verfahrenstechnik zur Förderung und Homogenisierung von hochviskosen Flüssigkeiten, wie z.B. Kunststoffschmelzen verwendet. Experimente und numerische Berechnungen zeigen, dass bei schleichenden Strömungen hochvikoser Fluide mit geringer thermischer Leitfähigkeit $(Re \to 0, Pe \geq 10^4)$ die Entwicklung des Strömungs- und des Temperaturfeldes auf verschiedenen Orts- und Zeitskalen stattfindet. Zudem wird aufgrund der hohen Viskosität die zur Förderung notwendige mechanische Energie zu einem großen Teil im Fluid dissipiert. In Kombination mit der geringen Wärmeleitfähigkeit führt dies zur Ausbildung eines inhomogenen und instationären Temperaturfeldes in der Flüssigkeit. So kann es passieren, dass die Kunststoffschmelze in Extrudern lokal so stark erhitzt wird, dass die physikalischen Eigenschaften des Materials sich irreversibel verändern. Dieser Vortrag stellt die Vorgehensweise und die Ergebnisse der numerischen Strömungs- und Temperaturfeldberechnung in einem Doppelschneckenextruder vor. Dazu werden dynamische d.h. zeitlich veränderliche Netze verwendet. Das strukturviskose Verhalten sowie die Temperaturabhängigkeit der Viskosität des Fluids fließen in die Berechnung ein. Die gewonnenen Ergebnisse in Abhängigkeit der Betriebsparameter werden diskutiert und mit experimentellen Daten einer Modellflüssigkeit verglichen.

Experimental validation of a visco-elastic material model for numerical simulation of the extrusion process of rubber blends. **Herbert Müllner** (TU Wien, Austria), André Wieczorek (TU Wien, Austria), Pia Petracek (TU Wien, Austria), Josef Eberhardsteiner (TU Wien, Austria) GA/CT1923/010

The dimensioning of injection heads for the extrusion of rubber profiles is exclusively based on empiric knowledge of the non-linear viscoelastic flow behavior of elastomers. Thus, the design of injection heads is carried out with subject to the used rubber blend, whereas the geometry of the appropriate profile is achieved by empiric adaptation of the extrusion die. The non-reproducible process technology affects the capacity of the running production relevantly. This work was performed in cooperation with Semperit Technische Produkte GmbH, which provided the rubber blends as well as the experimental devices.

An important task of a constitutive material characterization is the determination of a viscosity function, which can be used for arbitrary parts of instruments for the production of rubber profiles. Till now, capillary-rheometry is the most important method for the determination of the viscosity of common rubber compounds as well as rubber blends. Due to application problems for the investigated rubber blends, new concepts were developed for the identification of its viscoelastic properties without using correction methods [1].

From numerical simulations with variable power law constants material independent diagrams are obtained. For the validation of the new parameter identification a comparison between performed measurements and the numerical simulations of the corresponding situation is chosen. The simulations have been performed with the commercial CFD program POLYFLOW.

Therefore, all important state variables have been discussed, as experimental quantities like melt pressure and die swell measurements. The experimental validation of various capillary experiments shows good agreement between the results of the characterization methods [1] and the numerical simulations.

Drop deformation under surfactants adsorbtion. **Ioan-Raducan Stan** (Universitatea Babeş-Bolyai, Romania), Maria Tomoaia-Cotisel (Universitatea Babeş-Bolyai, Romania), Aurelia Stan (Cluj-Napoca, Romania) GA/CT3257/010

The movements of free liquid drops resulting from unbalanced surface tension gradients constitute important surface phenomena (Marangoni effect). It is well-known that a free liquid drop, submerged in an immiscible liquid undergoes complicate motions, when an interfacial tension gradient arises on their surface (in our case the adsorbtion of a surfactant). So linear and rotational displacements of the drop, oscillations, surface waves, deformations (even fission), have been experimentally evidenced. Theirs study is of present interest in the mass transfer processes, in conceiving models of movement at the biological membrane level, as well as in the space science and technology of liquids.

The aim of this paper is to correlate the effect of pressure forces on the drop, with the surface coverage degree, namely on the extent to which the drop surface is covered with surfactant. Our model show that for a covered degree less then 680, these forces are negative, this means that the force exerted by the external liquid upon the drop is oriented towards the negative direction of the normal to the drop surface, acting like a hammer.

We consider that is a direct connection between this force and the deformation of the drop. We showed that at small values of this force the drop remain undeformable, while for large values of force deformations and even fission of the drop may appears. However, there is more mechanism through which surfactants change the drop deformation. We mention here surface dilution, tip- stretching and capillary forces, but they appears as o consequence of the increase of the surface area of the drop when it is deformed to a nonspherical shape by the hammer force. The existence of this hammer force caused by the adsorbtion of a surfactant is in good agreement with our experimental data for different tension gradients and viscosities.

Linearized description of the flow of a vapor with condensation and evaporation through a micro-porous membrane. **Thomas Loimer** (TU Wien, Austria) GA/CT2701/010

The one-dimensional flow of a fluid near saturation through a micro-porous membrane is considered. Upstream of the porous membrane the fluid is in a state of saturated vapor. Downstream, the fluid is in a state of unsaturated vapor. Due to the Joule-Thomson effect, the fluid is cooler at the downstream side of the membrane than at the upstream side. Due to the temperature difference and the heat conduction in downstream direction, the saturated vapor condenses fully or partially and the fluid re-evaporates further downstream. The flow process is described taking into account (i) the temperature difference due to the Joule-Thomson effect, (ii) the capillary pressure across curved menisci in the porous medium and (iii) the vapor pressure reduction at curved menisci given by Kelvin's equation. Depending on the material properties of the fluid and the membrane and on the pressure difference, nine different types of flow occur. These types of flow are distinguished by the location of the condensation and evaporation fronts and whether the fluid condenses fully or partially. The different flow types are presented and a map is drawn to show the conditions under which they occur. The mass flux through the porous membrane is calculated and a comparison is made with experimental data.

Mathematical modelling of impregnation process. **Iryna Tkachenko** (Dnipropetrovs'k National University, Ukraine) GA/CT3806/010

Impregnation processes are an important part of many modern technologies dealing with porous media. As a rule the ŞdryŤ and ŞwettedŤ parts of porous body are separates by narrow domain which is called impregnation front or impregnation boundary and assumed asymptotically thin. Thus the impregnation process is described by moving boundary problem. Let us assume that the porous media in the considered problem is homogeneous and saturated in the ŞwettedŤ part, the impregnating liquid is incompressible, Darcy low takes place for filtration flow and then the filtration flow is described by Laplace equation with respect to pressure. The caution of the impregnation process is so-called wetting force that is capillary effect, which creates a pressure jump (called capillary height) on the impregnation front. At the first stage of the investigation a problem about the impregnation of spherical and cylindrical bodies which were instantly submerged into the liquid was considered. It is supposed that the impregnation process is regular. This assumption excludes from consideration an initial stage of impregnation process. The gas domain remains inside the body during the process. This domain is filled by the gas, which was in the body before the submerging. The process of impregnation continues until the gas pressure has become equal to the liquid pressure plus capillary height. In the considered case the pressure changes only along the bodyŠs radius. Then the boundary-value problem for Laplace equation is reduced to boundary-value problem for second order ordinary differential equation. Beside of that, Cauchy problem must be formulated to describe a motion of impregnation front. The analytical solutions for both cases are obtained. The next stage of the present work is solution of the same problems but in two-dimensional and three-dimensional formulation. Cartesian coordinates system is used in these cases. An analytical solution of two- and three-dimensional problems is very difficult and really possible for only very restricted number of cases. That is why the problems must be analyzed by some numerical method. It is well-known that the boundary element method is especially effective for elliptical boundary-value problems with linear differential operator, because the process of numerical solution is localized on the boundary alone. More than that, if there is a non-linear boundary condition, it gives additional advantages to boundary element method in comparison with other numerical methods. Zero order boundary element method is used in the present work. The considered above examples of analytical solutions are used as test problems during algorithm and computer code development. The proposed approach is illustrated by several examples of numerical calculations.

Investigations on damping behaviors of lateral excited liquid in cylindrical propellant vessels. **Tim Arndt** (Universität Bremen, Germany) GA/CT2344/010

Liquid sloshing represents an undesired phenomenon concerning most applications for fluid management in Space Transportation Systems (STS). Since the liquid propellant necessary to boost the STS from Earth surface to its orbital position is the most significant weight fraction influencing the attitude control, in particular the damping behavior of excited space propellant is from major interest. In our current work, we investigate the experimental damping behaviors using cylindrical tank geometries including the most prevalent flat, convex, and concave bottom profiles. During the experiments, the test liquid is driven close to their eigenfrequencies for certain fill levels. Then, the excitation is stopped, so that the sloshing

motion can decay. Damping characteristics are determined from sloshing forces that are acquired by load cells under the tank and from wave amplitudes mapped by the sloshing liquid surface on the tank wall. As a result, it can be shown, that the damping characteristics of sloshing liquid are directly connected to the varied fill level for all applied vessel geometries. Our conclusions are correlated to numerical simulations using commercial CFD solver.

A stall delay model for rotating blades. **Horia Dumitrescu** (Romanian Academy, Bucharest), Vladimir Cardos (Romanian Academy, Bucharest) GA/CT626/010

Even for the case of quasi-steady conditions the aerodynamic forces on a radial strip of the blade can be different than equivalent two-dimensional forces derived from two-dimensional wind tunnel tests or two-dimensional calculations. This difference is often called a three-dimensional effect, than can have several causes. Firstly, a wind turbine blade has a finite length and there will be end effects at the tip and at the root. The effect of finite span results in lower aerodynamic forces and appears in both non-rotational and rotational conditions. Therefore, this could be called non-rotational three-dimensional effect, essentially of non-viscous nature. But, what is more important for a wind turbine blade is the three-dimensional effect or rotation. The blade rotation causes large span-wise pressure gradients and the flow will be affected by centrifugal and Coriolis forces. This results in the augmentation of aerodynamic forces and could be called rotational three-dimensional effect, essentially of viscous nature. The paper investigates the boundary-layer characteristics on a wind turbine blade of small chord length. The three-dimensional form of momentum integral equations is derived and used to predict the boundary-layer growth and limiting streamlines angles on the blade surface for both attached and separating flow. The chordwise skin friction coefficient is used to identify boundary layer separation and shear layer reattachment locations. The nature of flow near to the axis of rotation is discussed ad a stall-delay is proposed.

Fluctuation measurements in the boundary layer of a supersonic flow. **Birgit Lenz** (Universität Stuttgart, Germany), Uwe Gaisbauer (Universität Stuttgart, Germany), Ewald Krämer (Universität Stuttgart, Germany) GA/CT3816/010

In recent years, a special constant temperature hot-wire anemometer (CTA) has been developed at the Institute of Aerodynamics and Gas Dynamics (IAG) of Stuttgart University in cooperation with the company Cosytech GmbH and the Institute of Theoretical and Applied Mechanics (ITAM) in Akademgorodok, Russia. This anemometer features a high cut-off frequency and the possibility to switch between a certain number of preset overheat ratios in a scanning procedure. Due to the dependence of the hot wire's sensitivity towards mass flow and total temperature fluctuations on overheat ratio, these quantities can be determined in one single measuring step. Additionally, the fluctuation levels of pressure, density and velocity may be calculated by Kovásznay's modal analysis.

The application of the hot-wire anemometer inside the boundary-layer afforded certain corrections in the data analysis developed for free-stream measurements: Firstly, the existing model for the anemometer transfer function had to be extended by comprehension of inductances of cable wires, frequency-dependent gain and the hot wire time constant. Secondly, a temperature correction was introduced, to account for the non-constant total temperature profile inside the boundary layer.

Experiments took place in the middle-sized supersonic wind tunnel (HMMS) of IAG, at a Mach number of 2.5. First measurements were undertaken at a flat plate, subsequent ones are taken in the near-shock region at a ramp configuration. For necessary corrections in the CTA hot-wire analysis, the profile of the boundary layer was determined simultaneously to the fluctuation measurements at the correspondent wall distance. Hereby, the temperature profile was achieved via a cold wire and the velocity profile via a Pitot tube.

GA/CTS4878/10: Flow stability and transition.

Organiser: Ewald Krämer (Universität Stuttgart, Germany)
Co-organiser: Guenter Brenn (TU Graz, Austria)

Stability analysis of the flow in a wetting/dewetting (micro-)gap. **Peter Ehrhard** (Universität Dortmund, Germany), Sabine Strein (Forschungszentrum Karlsruhe, Germany) GA/CT3477/010

Dynamic wetting or dewetting is important in many technical coating processes, like the production of photographic films or liquid-crystal displays (LCDs). In these production processes, for economical reasons, a fast and steady coating of a liquid onto a solid is of great importance. In such coating processes, however, an unstable contact line is observed beyond a critical coating velocity, causing air entrainment and, subsequently, a poor quality of the coating layer. In detail, the straight dynamic contact line takes a saw-tooth form in this unstable regime. This instability of the contact line may be caused by the instability of the flows on either side of the interface. For a prediction of the critical velocity, hence, it appears desirable to evaluate the stability of these flows.

In this study we concentrate on the flow in the convergent gap between the moving substrate (solid) and the free interface. This flow is responsible for the removal of air from the substrate, before the liquid can contact the substrate. The base flow is considered two-dimensional, steady and incompressible, featuring two basic pattern. In a first step we idealize the free interface as geometrically-fixed and approximate the kinematic boundary conditions reasonably. The idealized base flow is subjected to small 3-D and time-dependent perturbations. The governing equations are mass and momentum conservation, formulated in cylindrical coordinates within a radially-unbounded domain. We discuss stability results, obtained for various base flows and various geometric forms of the free interface. Further, an outlook towards a more precise modeling of the free interface is given.

Towards the problem of hydrodynamic stability of dispersed flows. **Alexander Osiptsov** (Moscow State University, Russian Federation), Sergei Boronin (Lomonosov Moscow State University, Russian Federation) GA/CT639/010

In the framework of a two-fluid model, we consider the linear stability of three plane-parallel flows of a viscous fluid with spherical inclusions, namely, a two-phase boundary layer on a flat plate and upward and downward channel flows of a viscous dusty gas in the presence of the gravity force. In the classic formulation of the linear stability problem given by P. Saffman for dusty flows in 1961, only the Stokes drag was taken into account in the interphase momentum exchange and, in the basic steady-state flow, phase velocity slip and particle concentration nonunifromities were neglected. The aim of our study is to develop the formulations of the linear-stability problem for dispersed flows with account for possible nonuniformities of the basic particle concentration profile, shear-induced lifting forces acting on the particles in locally shear flows, and

a possible phase velocity slip in the basic flow. For the flows considered, linearized equations of the two-fluid model are reduced to a modified Orr-Sommerfeld equation with several extra terms describing the feedback effect of the particles on the carrier flow, which significantly complicate the traditional formulation of the problem. The corresponding eigen-value problem is solved using an orthonormlization method with controlled accuracy. A parametric study of neutral-stability curves is performed. It is shown that the new factors considered may drastically change the limits of the laminar flow regime even at fairly small particle mass concentrations. For instance, in the two-phase boundary layer the lifting forces may result in the splitting of the instability region and a sharp decrease in the critical Reynolds number, while in the downward channel flow the gravity-induced velocity slip may result in the complete suppression of small perturbations. The problem of so-called critical layers will also be discussed in the presentation.

Instability mechanisms in bouyant-thermocapillary liquid pools. **Ulrich Schoisswohl** (TU Wien, Austria), Hendrik Christoph Kuhlmann (TU Wien, Austria) GA/CT3319/010

A cylindrical volume of fluid, with a free surface on top, is heated by a parabolic heat flux from above. Two physical effects drive a bouyant-thermocapillary flow. On the one hand temperature gradients on the free surface, introduced by the heat flux, and on the other hand bouyancy forces, due to gravity. The basic axisymmetric flow is computed by finite volumes and its stability is investigated by a linear stability analysis. It is found that the critical stability boundaries and the critical modes are quite similar to those which are well-known from the half-zone model of crystal growth.

For low Prandtl numbers the critical mode is steady and three-dimensional. We find an asymptotic critical value in the limit of vanishing Prandtl number. For increasing Prandtl number the critical Reynolds number increases. Near unit Prandtl number no threshold could be found with the present computational limitations. For Prandtl numbers larger than unity, the critical mode is oscillatory and the critical Reynolds number decreases with the Prandtl number. The low- and high-Prandtl-number instabilities are caused by different instability mechanisms. We present evidence that the low-Prandtl-number instabilities are essentially centrifugal and that the high-Prandtl-number instabilities are due to the hydrothermal-wave mechanism.

Experiments on the transition to 3D-flow structures in two-sided lid-driven cavities. **Tanja Siegmann-Hegerfeld** (TU Wien, Austria), Stefan Albensoeder (Universität Bremen, Germany), Hendrik Christoph Kuhlmann (TU Wien, Austria) GA/CT2869/010

Flow instabilities in two-sided lid-driven-cavities are investigated. The flow is driven by the tangential motion of two opposite walls which are realized by cylinders of large radii in the experimental setup. The transition of the nearly two-dimensional flow to three-dimensional flow structures is investigated for the one-sided, the parallel and the anti-parallel motion of the driven walls. The Reynolds numbers of both sides have been varied between ± 1200. The geometry is characterized by the cross-sectional aspect ratio Γ and the spanwise aspect ratio Λ. Two aspect ratios ($\Gamma = 1$ and $\Gamma = 0.76$) have been investigated. The spanwise aspect ratio of $\Lambda > 10$ is sufficiently large to to minimize end-wall effects. Qualitative results have been obtained by using visualization techniques. Furthermore, LDA and PIV measurements have been conducted to obtain quantitative results. Depending on the Reynolds numbers nearly two-dimensional steady flows as well as steady and time-dependent three-dimensional flows are analyzed. We have characterized six different three-dimensional flow pattern. Each of them corresponds to a certain critical mode of previous numerical stability analyses. In most cases the experimental critical Reynolds numbers, flow structures, velocity profiles, and bifurcation diagrams are in very good agreement with the corresponding numerical predictions.

A preliminary study of the effect of the external stream structure on turbulent spots generation during bypass transition. **Pavel Jonas** (Institute of Thermomechanics Academy of Sciences, Czech Republic), Witold Elsner (TU Czestochowa, Poland), Marian Wysocki (TU Czestochowa, Poland), Vaclav Uruba (Czech Academy of Sciences, Czech Republic), Oton Mazur (Institute of Thermomechanics Academy of Sciences, Czech Republic) GA/CT1826/010

It was clearly proved that not only the turbulence level of the external flow but also the turbulence length scale influence the start and the end of boundary layer by-pass transition; e.g. Jonas et al., Eur. J. Mech. B Ű Fluids 19, 2000, 707-722. An elaborated physical notion on the role of the external turbulence length scale in transition process is not yet available. The characteristic feature of laminar-turbulent transition process is the appearance of turbulent spots followed by calmed regions, well defined structures that dominate the last stage of transition. So the investigation of the formation and development of turbulent spots can explain the effect of length scale on transition process. The experiment was executed on a flat plate boundary layer at different external flow turbulence scales of velocity and length (ERCOFTAC Test Case T3A+). Special methods were developed and applied for the instantaneous wall friction measurement and for the conditional analysis of wall friction records. Additionally, a special spot detection method developed by Elsner et al., Chemical and Process Eng. Vol. 27, 2006, 935-950 was applied. This method utilizes a wavelet analysis to detect particular frequency components and to localize spot occurrences in time.

Experiments on the laminar/turbulent transition of liquid flows in rectangular micro channels. **Peter Ehrhard** (Universität Dortmund, Germany), Wolf Wibel (FZ Karlsruhe, Germany) GA/CT3480/010

The advances of micro-fabrication techniques allow for the manufacturing of micro heat exchangers or micro reactors. These micro devices are characterized by a large surface-to-volume ratio and, hence, allow for the transfer of large heat fluxes or offer large katalytic surfaces for reactions. The design and optimization of such micro devices heavily relies on correlations for pressure drop and heat transfer, as well as on information on the laminar/turbulent transition. As these questions are still discussed controversially in literature, a careful investigation appears highly desirable.

We concentrate onto rectangular stainless steel micro channels with a hydraulic diameter of $d_h \simeq 133\,\mu\mathrm{m}$. Three aspect ratios are engaged, namely 1:1, 1:2, 1:5, whereas the hydraulic diameter is kept constant. The roughness of the channel walls is $k \simeq 1\text{–}2\,\mu\mathrm{m}$ in general, specific channels are of roughness $k \simeq 25\,\mu\mathrm{m}$. Filtered and degassed de-ionized water is driven at pressure differences up to $20\,\mathrm{bar}$ through the channels, allowing for Reynolds numbers up to $\mathrm{Re} \simeq 4000$. The measuring techniques allow for a highly-accurate determination 1. of the mass flow rate (precision weighting), 2. of the temperatures at inlet and outlet, 3. of the pressure drop, and 4. of the time-resolved velocity field (μPIV).

We find from all measured quantities, consistently, the laminar/turbulent transition for smooth channels in the range $\mathrm{Re}_c \simeq 1900\text{–}2200$, in agreement with findings for macroscopic channels. The influence of rough channel walls appears particularly strong for the micro channels of aspect ratio 1:5 ($\mathrm{Re}_c \simeq 900$). This raises the question, whether the dimensionless group (k/d_h) remains the relevant parameter at extreme aspect ratios.

Capillary hydrodynamics of the deposition of thin liquid films and droplets on heterogeneous, porous substrates. **Daniel Gerlach** (Universität Erlangen–Nürnberg, Germany), Norbert Alleborn (Universität Erlangen–Nürnberg, Germany), Antonio Delgado (Universität Erlangen–Nürnberg, Germany), Hans Raszillier (Universität Erlangen–Nürnberg, Germany) GA/CT4112/010

The paper to be presented will deal with recent research work on capillary hydrodynamics of thin viscous liquid films and droplets. The process engineering background comes from industrial processes to deposit thin films or droplets on substrates such as polymer foils or paper [1].

In the first part, the fluid dynamics of thin viscous liquid sheets, which are used to deposit liquid films in curtain coating, is investigated. The focus will lie on the propagation of disturbance signals in a uniformly thin viscous liquid sheet of infinite extent which is in contact with a passive ambient medium. The disturbances considered are induced by local external pressure perturbations moving on the sheet interfaces. The tool of analysis is the Fourier-Laplace transform of the linearized perturbation equations, and the inverse Fourier-Laplace transform for the numerical reconstruction of the amplitude of the interface deflections. Symmetric (varicose) and antisymmetric (sinuous) disturbances are investigated in the long time limit by numerical signal evaluation. The exact disturbance responses are compared with their longwave approximations [2].

The second part will investigate the fate of films and droplets on heterogeneous, porous substrates *after* their deposition in a coating process. Besides the fluid dynamics *on top of* the substrate, the capillary transport of fluid *inside* the porous substrate will be considered. The dynamics of the fluid on the substrate surface is treated in the framework of lubrication approximation. Fluid flow within the porous substrate, caused by the droplet penetrating into it, is treated in the framework of Richards' equation, which models *unsaturated flow* in porous media. Numerical results for sorption of films and droplets into a substrate of finite thickness show the influence of the sorption characteristics of the porous material on the final fluid distribution within the substrate. The interplay of fluid properties and wetting and sorption properties of the substrate hereby offers the possibity of a controlled structuring of surfaces, e.g. in microsystem technology [3].

Influence of the bottom undulation on surface waves in thin film flows. **Christian Heining** (Universität Bayreuth, Germany), Andreas Wierschem (TU München, Germany), Nuri Aksel (Universität Bayreuth, Germany) GA/CT2149/010

We study viscous gravity-driven thin films flowing down an undulated plane. Applying the integral boundary-layer method we derive a set of coupled PDEs for the film thickness and the flow rate. The steady state solution shows linear and nonlinear resonance. Based on this analytical solution we carry out a stability analysis with respect to surface waves and study wave generation and annihilation.

Soap bubbles: an illustration of potential flow theory and the Dirichlet problem. **Josué Sznitman** (ETH Zürich, Switzerland), Thomas Roesgen (ETH Zürich, Switzerland) GA/CT2381/010

There are few physical objects as beautiful and fascinating as soap bubbles. They exhibit a perfection of geometrical form and an appealing simplicity. Soap bubbles are characterized by the structure of their thin liquid shell of low surface tension. It is well known that the dynamics of the surface of soap bubbles are the resultant of both 1) liquid film thinning under the influence of gravity, and 2) the presence of local surface tension gradients which create complex flows (Marangoni flows). In turn, the net motion of the thin liquid shell induces the displacement of gas inside the cavity due to the no-slip boundary condition which holds at the liquid-gas interface. Both flows on the liquid shell and within the cavity are incompressible. Moreover, the boundary-driven internal cavity flows are viscosity-dominated such that they are effectively governed by the equations of creeping motion.

While soap bubbles exhibit intrinsic internal flows, thermally-induced Marangoni flows in the liquid film may lead to steady-state forced recirculation inside the cavity. Experimentally, this may be achieved by applying a thermal gradient in the vicinity of the liquid shell. Because most liquids maintain a negative and constant value of $d\sigma/dT$, where σ is the surface tension and T the temperature, the application of a constant thermal gradient produces a fixed shear stress at the liquid surface given by $\tau = \mathrm{d}\sigma/\mathrm{d}\underline{x} = (\mathrm{d}\sigma/\mathrm{d}T)(\mathrm{d}T/\mathrm{d}\underline{x})$, where $\underline{x}$ relates to the spatial direction. Thus, a fixed-shear stress on the shell boundary will lead in turn to steady-state flows in the liquid shell and within the cavity itself following conservation of mass. In the present discussion, we will show experimental flow visualizations of the boundary-driven cavity flows inside soap bubbles, which may be controlled by such thermal forcing schemes. Variations in the number and location of heat sources applied near the liquid shell effectively yield different internal flow topologies. Such steady-state flows on the surface of the shell and within the soap cavity may be mathematically modeled using potential flow theory by solving the Laplace equation, $\triangle\Phi = 0$, for the flow potential Φ on the boundary and within the cavity. In particular, soap bubbles illustrate here the well-known Dirichlet problem for a sphere, where flow on the boundary of the sphere is prescribed by the forced motion of the liquid shell and flow within the spherical boundary is then solved for.

Finite-volume simulation of blood flow through complete bypass models. **Jan Vimmr** (University of West Bohemia, Czech Republic), Alena Jonášová (University of West Bohemia, Czech Republic) GA/CT2498/010

It is proven that the *intimal hyperplasia* (IH) is the main reason for the late failure of bypass grafts due to the restenosis of the anastomosis between the graft and the blood vessel. Hence the influence of hemodynamics on the occurrence of IH should be analyzed in form of recirculation zones, eddies, low and oscillating Wall Shear Stress (WSS) and large spatial Wall Shear Stress Gradient (WSSG). In this study these factors are analyzed for a blood flow through a 2-way bypass graft in comparison to the traditional 1-way bypass graft. The effect of the junction angle and bypass graft diameter in both types is observed by various degree of stenosis of the host tube including the fully blocked case as the final phase of the atherosclerosis.

The problem of the blood flow through a complete bypass model with rigid walls is solved as an isothermal laminar flow of viscous Newtonian fluid using the incompressible Navier-Stokes equations. The calculations are based on the cell-centered finite volume method. The time marching scheme employs a predictor-corrector technique using a variable time step. The traditional 1-way bypass model is based on the study elaborated by Lee et al. (2001), which includes the proximal and distal parts of the host tube together with the end-to-side bypass graft. The resulting velocity and pressure distributions in the idealized models are obtained for steady and physiological pulsatile flows by varying Reynolds and Womersley numbers.

Numerical simulation of the endolymph flow in the semicircular canals of the vestibular organ. **Dominik Obrist** (ETH Zürich, Switzerland), Leonhard Kleiser (ETH Zürich, Switzerland), Stefan Hegemann (Universitätspital Zürich, Switzerland) GA/CT1994/010

The semicircular canals are the primary human sensors for angular motion. They are part of the vestibular organ which is located in the inner ear. The semicircular canals are filled with a fluid called the endolymph. Movements of the head induce a flow of the endolymph. This flow deflects an elastic gelatinous structure (cupula). The deflection of the cupula triggers nerve signals resulting in the perception of angular motion.

A detailed understanding of the fluid dynamics of the endolymph is indispensable for the study of diseases of the semicircular canals (e.g., various forms of vertigo). Several authors have presented idealized models for the endolymph flow. All of these models, however, reduce the problem to zero- or one-dimensional equations which do not appreciate the full complexity of this configuration.

We present early results from a numerical simulation of the endolymph flow in a two-dimensional representation of the semicircular canals. Here, the endolymph flow is described as a Stokes flow in a complex annular structure, i.e., a semicircular canal. The reactive force of the elastic cupula onto the endolymph enters the Stokes equations as an external force. The highly transient character of this flow (due to the angular motion of the head and the fluid-structure interaction between the endolymph and the cupula) requires a careful treatment of the different time-scales.

The dynamics of the cupula is simulated by an explicit time-integration scheme. Within each time-step we solve the quasi-steady Stokes equations for the endolymph with the method of fundamental solutions. The transient motion of the head leads to time-dependent boundary conditions. This numerical scheme is examined for its accuracy, robustness and computational efficiency.

Numerical solution of the incompressible Stokes equations with explicit integration of the pressure term. **Giuseppe Bonfigli** (ETH Zürich, Switzerland) GA/CT2323/010

The numerical integration of the Navier–Stokes equations for incompressible flows has always been a central topic of numerical fluid mechanics. One possible approach consists of computing the pressure p and the velocity vector $\underline{u}$ (primitive variables) at discrete grid points by solving a system of algebraic equations obtained by discretization of the governing differential equations. After discretization in time, easy analytical manipulations provide a decoupled Poisson equation for p and Helmholtz or algebraical equations, depending on the time integration scheme, for the velocity components. However, while the boundary conditions for $\underline{u}$ are clear, those for p are still subject of controversial debate.

We developed a formulation of the incompressible Navier-Stokes equations which considers boundary conditions for the p-Poisson equation obtained from the boundary-normal component of the momentum equation. The new formulation is suitable both for explicit and implicit time integration of the viscous terms, while pressure and non-linear terms are always integrated explicitly. In all cases the computational problems for the pressure and for the velocity components are decoupled. Strong similarities exist with respect to the formulation proposed by Johnston & Liu (JCP, 2004). However, our method is improved by the introduction of an additional term in the p-Poisson equation and by a new Neumann boundary condition for the boundary-normal component of the velocity. Both aspects are important to ensure the decay of eventual errors in the continuity equation.

The new formulation has been applied to the computation of a 2-D Stokes flow with unsteady boundary conditions. Spatial discretization was achieved by means of finite-differences. An explicit Runge–Kutta scheme or a semi-implicit Crank–Nicolson/Adams–Bashforth scheme were used for time integration. Convergence rates of the solution corresponded to the order of the considered discretization schemes.

High-order accurate solution of the incompressible Navier–Stokes equations. **Rolf Henniger** (ETH Zürich, Switzerland), Leonhard Kleiser (ETH Zürich, Switzerland), Dominik Obrist (ETH Zürich, Switzerland) GA/CT2382/010

We present a high-order simulation code for the incompressible Navier-Stokes equations which is suitable for massively parallel computers. It is based on a finite-difference discretization in space and a semi-implicit integration scheme in time. Velocity components and pressure are calculated on a staggered grid. The elliptical problem is solved in an iterative manner, split into inner and outer iteration cycles, such that the momentum and continuity equations are exactly satisfied. The inner iteration cycle is similar to a discrete Poisson problem with Neumann boundary conditions. We employ a multigrid procedure with either Jacobi or Gauss-Seidel smoothing for its solution. Non-periodic boundaries are handled explicitly or (partially) implicitly. In addition, the rate of convergence is accelerated by a Krylov subspace method (BiCGStab) which utilizes the multigrid algorithm as a preconditioner. We investigate the efficiency of the nested iteration cycles with respect to the timestep size, the Reynolds number, the spatial resolution and different multigrid parameters for a channel flow configuration.

Viscosity in discontinuous Galerkin methods. **Manuel Keßler** (Universität Stuttgart, Germany) GA/CT3805/010

In technical fluid applications viscosity plays an important, and often dominant, role for the flow phenomena at interest. Moreover, as these applications feature high Reynolds numbers and thus in general turbulent flow, turbulence modeling of some kind or another is the only affordable alterntive, as LES or even DNS are usually prohibitively expensive. Any approach to simulate such flows therefore needs to take viscous effects into account.

Discontinuous Galerkin (DG) methods have gained some interest in recent years, as they deliver high order on unstructured grids, have little requirements on grid quality, excellent adaptation and parallelisation properties and a computational pattern suitable for the ever spreading clusters of scalar commodity processors.

However, second and higher derivatives, and thus viscosity and turbulence models, and DG do not mix—at least not very well. The mathematical framework is rigorous for first derivatives, but basically undefined for higher ones. Fortunately, nature teaches us that the problem at hand is well posed indeed, and therefore solutions should be possible.

One remedy is to reformulate the equations as a first order system, introducing the needed derivatives as independent variables of their own. While this so-called Local DG (LDG) is the mathematically cleanest way, the explosion of solution variables—e.g. from 7 to 24 in three dimensional $k-\omega$ simulations—often is too expensive, especially for implicit time integrations, where the memory increase is even more pronounced.

Another approach starts from the same considerations, but evaluates the additional terms with some approximations for the surrounding region. The main point here, introduced by Bassi and Rebay, is to decompose the discrete derivative into a part based on the local polynomial exact derivative in the cell interior, which is easily computable, and another one caused by the discontinuity jumps between cells. The latter increases the computational stencil by the surrounding cells, but allows one to get rid of the explicit storage of derivatives and instead compute them on the fly, along with the flux computation.

Once second derivatives are integrated into the DG framework efficiently, viscous simulations are no further difficulty for DG. However, due to the high order nature of the method, modifications on the turbulence model may be beneficial, in order to take advantage of the rich structure available in the polynomial solution representation in each cell. Concept and efficiency of such modifications are an area of active research.

Numerical modelling of turbulent flow over rough walls. **Petr Louda** (CVUT v Praze, Czech Republic), Karel Kozel (CVUT v Praze, Czech Republic), Jaromír Příhoda (Czech Academy of Sciences, Czech Republic) GA/CT1679/010

The numerical simulation of turbulent flow over rough walls was carried out for various types of roughness. The mathematical model was based on the Reynolds averaged Navier-Stokes equations for incompressible flow. The two-equation k-ω/k-ϵ SST model proposed by Menter and the one-equation model according to Spalart and Allmaras were used. The system of governing equations was solved by the artificial compressibility method. The cell-centered finite volume method with the third order upwind interpolation for convection term and the second order central scheme on dual grid for diffusion terms were used for the space discretization. The time discretization was carried out by the implicit backward Euler scheme with the Newton linearized system solved iteratively. Boundary conditions on rough walls were prescribed by wall functions and/or directly on the wall using the SST model modified to account for wall roughness by Hellsten and Laine (1997) and the SA model modified by Aupoix and Spalart (2003). Turbulence models were tested for the constant-pressure turbulent boundary layer on the rough wall formed by commercial abrasive paper and by tightly-packed spheres. The dependence of the velocity shift in the logarithmical region on the wall-roughness type was studied for transitional and fully-rough regimes. Besides, the effect of wall roughness on the decelerated flow over a smoothly contoured ramp with flow separation was investigated. Obtained results were compared with experimental data.

On a new numerical algorithm for the solution of triple deck problems. **Rene Szeywerth** (TU Wien, Austria), Alfred Kluwick (TU Wien, Austria) GA/CT1845/010

A new algorithm for the solution of laminar viscous-inviscid interactions allowing for the formation of pronounced separation zones is presented. It is then applied to two different types of flows: near critical two layer fluid flow and subsonic flow past an expansion ramp. In the first case emphasis is placed on the formation of so-called non-classical hydraulic jump having the distinguishing property that waves pass through rather than merge with the jump. The second problem exhibits the interesting feature that no solution exists if the ramp angle exceeds a critical value while two solutions exists if the ramp angle is subcritical. The new numerical scheme is used to study the change in the flow behaviour as the critical ramp angle is approached.

Moving-mesh approach for solving Reynolds' bearing equation. **Bernhard Schweizer** (Universität Kassel, Germany) GA/CT4298/010

Basis of the hydrodynamic bearing theory is the Reynolds bearing equation. In its original form, the Reynolds equation is a linear partial differential equation for the calculation of the pressure distribution in the bearing. To solve this equation, boundary conditions have to be applied which must take into account cavitation effects. When using the so-called Reynolds boundary conditions, the governing boundary value problem is nonlinear. Various methods exist to solve this problem. Here, a new method based on an ALE-approach is presented.

Release dynamics of liquefied gases from pressure storage tanks. **Jean Paul Kunsch** (ETH Zürich, Switzerland) GA/CT1758/011

Storage tanks with pressurized liquid gases such as propane or chlorine represent a substantial hazardous potential. The dynamics of a release through an opening or an accidentally generated puncture are studied. An important quantity to be determined is the time to empty the reservoir, since it represents the initial condition of the subsequent dispersion process. Another relevant quantity is the cooling of the liquid phase which influences the vapour pressure, which on its part represents a driving force of the outflow dynamics.

A perturbation method, taking the temperature dependence of the thermal quantities and of the vapour pressure into account, is proposed to describe the emptying of the storage tank. A first approximation based on constant vapour pressure but also higher-order solutions are presented. Their validity is discussed for commonly used gases with regard to risk assessment studies, where the release scenario represents an initial element in the chain of events.

Transonic viscous inviscid interactions in narrow channels. **Georg Meyer** (TU Wien, Austria), Alfred Kluwick (TU Wien, Austria) GA/CT1734/011

Transonic flows through channels which are so narrow that the classical boundary layer approach fails are considered. As a consequence the properties of the inviscid core and the viscosity dominated boundary layer regions can no longer be determined in subsequently steps but have to be calculated simultaneously. The resulting interaction problem for laminar flows is formulated for both perfect and dense gases. Representative solutions including the internal structure of pseudoshocks and the choking phenomenon will be presented.

Aerodynamic optimization of Laval nozzle flow with shocks: numerical investigation of active/passive shock control via expansion fans. **Nisar Al-Hasan** (TU München, Germany), Günter Schnerr (TU München, Germany) GA/CT1663/011

Instantaneous ignition in the supersonic part of a 3D Laval nozzle is realized by a well-defined sudden temperature rise across a normal shock. Unfortunately, the divergence of the supersonic nozzle part is necessarily smooth. Therefore, the turbulent boundary layer ahead of the shock is thick and causes substantial shock/boundary layer interactions. The non-homogeneous temperature increase across the shock, caused by the boundary layer thickening ahead of the shock and the resulting pre-compression prevents the quasi 1D evolution of the flow downstream. Additionally, due to the boundary layer thickness the single shock disintegrates in a so called *pseudo-shock system*; i.e., into a sequence of periodic weak compression and expansion regions.

To avoid this drawback and to establish homogeneous thermodynamic conditions throughout the entire cross section and flow domain downstream of the shock we apply active and passive control techniques in the area of shock boundary/layer interaction. The central idea of the control technique described below is compensation of the thickening of the boundary layer by quantitative appropriate inverse effects, i.e. by superimposing negative and positive pressure gradients in the near wall region close to the shock position.

In a first approach the additional expansion fan is created by active suction slots in flow direction and through all sidewalls of the 3-D nozzle. The resulting shock remains straight with exception of the near wall region. Suction creates an effective convex wall curvature. In supersonic flow the resulting local expansion tends to compensate the pre-compression. Because suction in high temperature environment is difficult to realize, we alter the wall curvature to create a *negative bump* with the same effect on the effective wall curvature. Under these conditions a single plane normal shock could be established without active or passive suction. The paper presents parameter studies for optimization of the operating conditions.

The effect of shock-wave/boundary-layer interaction on turbulent spot propagation. **Andreas Jocksch** (ETH Zürich, Switzerland), Leonhard Kleiser (ETH Zürich, Switzerland) GA/CT2499/011

We performed highly resolved Large-Eddy Simulations of transitional shock-wave/boundary-layer interactions (SW/BLI) in which a turbulent spot passes through a laminar shock-induced separation bubble. For discretisation we employ a sixth-order compact finite-difference scheme in space and a third-order Runge-Kutta time-marching scheme. Unresolved scales are treated by the Approximate Deconvolution Model using the relaxation term only (ADM-RT). The LES model is also engaged to handle the shock. The initial condition consists of a laminar boundary-layer solution on a flat plate with a superimposed oblique shock which induces a separation bubble on the plate. An upstream-positioned initial disturbance consisting of a localised vortex pair triggers the turbulent spot that develops downstream and eventually encounters the SW/BLI region. The separation bubble collapses during the spot passage and regains its undisturbed shape after the spot has passed. Unlike the laminar boundary layer, the turbulent region does not separate in the shock region. This phenomenon is described as tunneling of the turbulent spot through the SW/BLI region. Compared to a simulation without SW/BLI, the spot growth is increased significantly during the shock-region passage. Despite this influence, the characteristic shape of the spot is qualitatively maintained. This finding supports the results of previous DNS by Krishnan and Sandham (2004).

Large-eddy simulation of film-cooling. **Jörg Ziefle** (ETH Zürich, Switzerland), Leonhard Kleiser (ETH Zürich, Switzerland) GA/CT2476/011

In modern high-performance gas turbines, the hot gas from the combustor enters the turbine stages at temperatures that often exceed the material limits of the turbine blades. Therefore, they have to be protected, which is usually done by a technique called film-cooling in which a layer of cool air ejected through small holes near the leading edge of the blades shields their surface.

We performed time-dependent three-dimensional numerical simulations of the well-known film-cooling configuration of Sinha *et al.* In their experiments cold fluid was ejected through a row of short oblique nozzles into a relatively hotter turbulent adiabatic flat-plate boundary-layer. Our flow parameters were chosen according to case 10 of Sinha et al., with a jet-to-crossflow density ratio of 2, a jet-to-crossflow velocity ratio of 0.25, and a Reynolds number of 15875 (computed with the jet diameter and free-stream quantities). The non-resolved turbulent flow scales are taken care of by the approximate deconvolution model (ADM). In previous work, this subgrid-scale model was implemented into the simulation code NSMB, a finite-volume solver for the compressible Navier-Stokes equations. NSMB supports domain decomposition using grid blocks and is MPI-parallelised on the block level. In a series of LES of separated flow configurations with increasing complexity, the ADM code has been successfully validated and proven to work

very well for compressible flows featuring strong unsteady vortical structures.

The goal of this study is to evaluate the performance of the approximate deconvolution model for film-cooling applications, and to investigate the suitability of the simulation approach and the employed simplifications, e.g. the use of a mean turbulent boundary-layer profile instead of unsteady turbulent inflow data. Special focus is placed on the mixing properties in the near-field of the orifice as well as on the influence of buoyancy. We will support our findings with detailed visualisations of the three-dimensional time-dependent flow field, especially the vortical structures in the mixing region. Furthermore, we will study the flow conditions in the jet nozzle, especially the secondary flows, which are known to have a strong influence on the downstream mixing behaviour and thus the cooling efficiency.

Assessment of high-order discretization schemes for computation of compressible swirling mixing layers. **Sebastian Müller** (ETH Zürich, Switzerland), Leonhard Kleiser (ETH Zürich, Switzerland) GA/CT2401/011

We report on results obtained with a highly accurate Direct Numerical Simulation (DNS) and Large-Eddy Simulation (LES) code solving the (filtered) Navier-Stokes equations in cylindrical coordinates. The code computes a compressible swirling mixing layer (i.e. a circular mixing layer with an additional swirl component which is present only in the shear layer) at Mach number $Ma = 0.8$. This flow incorporates the nonlinear disturbance development and transition to turbulence of the laminar layer perturbed at the inflow by viscous spatial instabilities.

We will present two simulations differing in the spatial discretization schemes for the convective terms. One discretization is based on up to tenth order central compact finite differences in the radial and axial directions and a Fourier spectral method in the azimuthal direction, combined with an additional secondary filter operation (corresponding to $\hat{Q}_5\hat{G}$ in the ADM relaxation term) every second time step to ensure numerical stability. The other discretization uses upwind-biased schemes in all spatial directions.

Apart from varying the grid resolution, comparisons of flow simulations using different discretization schemes for otherwise identical conditions can be performed quantitatively and improve the understanding of the effects of numerical errors and in particular numerical dissipation. Furthermore they may contribute to improved estimates concerning resolution requirements in general flow situations.

The differences of the computational schemes will be shortly outlined. We will focus on detailed comparisons concerning flow statistics as well as on highlighting the small scale structures.

On fluid-structure interaction in transonic wind tunnels. **Bosko Rasuo** (University of Belgrade, Yugoslavia), Aleksandar Bengin (University of Belgrade, Yugoslavia) GA/CT894/011

This paper studies the interaction (influence) of perforated walls of transonic wind tunnels in two-dimensional investigations which employ the generalized method for solving DirichletŠs problem formulated for the rectangle of the transonic wind tunnel work section. In order to preserve the realistic features of the flow at the work sectionŠs perforated boundaries, the boundary conditions, which are required to solve this type of boundary problem, are experimentally determined by measuring the static pressure distribution in the vicinity of the walls of the work section. The algorithm has been applied to the aerodynamic experimental results from investigations of NACA 0012 airfoil obtained at the VTI -Aeronautical Institute and the Faculty of Mechanical Engineering in Belgrade to demonstrate in two-dimensional investigations the appropriateness of the presented advanced algorithm for the calculation of the interference of the transonic wind tunnel wall.

Aerodynamic characteristics of the propeller in non-axial flow. **Milan Vrdoljak** (University of Zagreb, Croatia) GA/CT3794/011

Flow on running propellers installed on aircraft in general case is not axial. This results in off-axis forces and moments at propeller which are treated here in form of aerodynamic coefficients. Importance of forces and moments of propeller in non-axial flow lies in the fact that they have significant influence on aircraft static stability.

Presented numerical model of the propeller is based on the vortex theory and it includes model of propeller wake. Lifting line method is applied for propeller blade model using set of discrete Π vortices. Free-wake method with relaxation technique is applied for determination of propeller wake described with discrete vortices forming vortex sheet from each propeller blade. Using this approach for propeller vortex wake roll-up, segments of blade trailing vortices coincide with streamlines. Since the results for blade circulation distribution are directly connected to the geometry of its vortex wake, complete model of propeller is composed of blade model and wake model which are applied successively.

Given model is applied for analysis of aerodynamic characteristics of a propeller under the angle of attack, or sideslip angle, or their combination. Results of presented model for off-axis forces and moments coefficients of propeller in non-axial flow are compared with experimental results and other analytical methods for particular propeller geometry. Presented low computational cost numerical model is suitable for implementation in component build-up method and could be used for prediction of propeller contribution to the aircraft aerodynamic characteristics.

New developments regarding supersonic flows over delta wings with supersonic leading edges. **Stefan Mihai Neamtu** (INCAS, Bucharest, Romania) GA/CT3196/011

Compact expressions of the perturbation velocities over delta wings with supersonic leading edges and their application for wing aerodynamic characteristics calculation are presented. The new expressions are developed in the framework of small perturbation conical flow theory and cover conical delta wing configurations of high order. The present abstract will be completed later with further details.

Numerical eigen-mode analysis of an acoustic-duct system by CFD-OLG and comparison against experiment. **Urban Neunert** (TU München, Germany), Jan Kopitz (Universität München, Germany), Thomas Sattelmayer (TU München, Germany), Wolfgang Wolfgang Polifke (TU München, Germany) GA/CT2153/012

Duct systems in engineering applications can be prone to wanted or unwanted acoustic resonances. Numerical methods are required to predict these phenomena in early design stages. One such method to describe the acoustic properties of an acoustic system is the 1-D network model, which combines the acoustic transfer matrices of all elements representing the system. Since the transfer matrices of all system elements have to be known, this method is often limited.

Another possibility is to simulate the complete system with compressible CFD. Although this allows the prediction of the acoustic behaviour of even highly complex geometries very precisely, it inevitably leads to often forbiddingly heavy computing efforts and high costs.

In previous work a combination of both methods has been presented, which combines their advantages and avoids the respective disadvantages. One rather small part of the system containing a complex element is simulated by detailed CFD with a non-reflecting boundary condition. The system answer is post-processed by a network model representing the other, geometrically rather simple, part of the system. The acoustic stability analysis is finally performed by determining the open-loop-gain.

The present work demonstrates the full capabilities of the CFD-OLG method by applying it to a complex geometry consisting of two ducts and a sudden change of area. The results are compared with analytical results and validated against experimental data. Very good agreement is achieved between the experimental results and those of the CFD-OLG method while the traditional network model is not able to match the quality of this agreement.

A multiple scales solution to the undular hydraulic jump problem. **Richard Jurisits** (TU Wien, Austria), Wilhelm Schneider (TU Wien, Austria), Yee Seok Bae (Changwon National University, Sud-Korea) GA/CT2253/012

Recently a steady-state version of a perturbed Korteweg–de Vries equation was proposed to describe the fluid's surface elevation in phenomena like the undular hydraulic jump in turbulent open channel flow. We consider the an equation of the form:

$$H''' + (H-1)H' - \beta H + \gamma = 0\,,$$

where H is the surface elevation as a function of the non-dimensional longitudinal downstream coordinate, β describes frictional damping and γ is a gravitational forcing term.

Exploring numerically the solutions of this in the parameter space (γ/β, $H(0)$, $H'(0)$ and $H''(0)$) one finds undular shapes of the surface with slowly changing amplitudes and wavelengths as well as singular surface shapes. To gain insight into the structure of the solutions, an asymptotic analysis for small values of β and γ is presented. A multiple scales approach is pursued, and the resulting undular solutions for the surface elevation are found to agree very well with numerical solutions. It is also shown that the singularities of the numerical solutions are associated with a breakdown of the corresponding undular asymptotic solutions. Considering the analytical properties of the multiple scales solution, sufficient conditions for the formation of an undular jump are obtained. Furthermore, the asymptotic behaviour of the undular jump solutions far downstream is investigated.

Finally, for the purpose of comparison, the full equations of motion of turbulent free-surface flow were solved with a commercial CFD-code using the standard $k-\varepsilon$ model. Based on an asymptotic analysis, an iteration scheme for the free surface was developed and successfully applied. The results of the analysis are also compared with experimental data, and satisfactory agreement is achieved.

Application of the Green's function technique and the modal analysis to predicting noise from a compact region of turbulence in a circular pipe. **Andriy Borisyuk** (Institute of Hydromechanics, Kiev, Ukraine) GA/CT413/012

A problem of noise production by a compact region of turbulence in an infinite straight rigid-walled pipe of circular cross-section is considered. The problem is solved via the use of the Green's function technique and the modal analysis. A turbulence region is modelled by the distributed quadrupole and dipole sources (whose characteristics are assumed to be known), and the cases of homogeneous and non-homogeneous turbulence are considered.

It is shown that the noise power does not decrease as the distance from the turbulent sources increases, and is a sum of the powers of the pipe acoustic modes. The acoustic mode power consists of the three parts. The first part is the power generated by the volume quadrupoles, the second part results from the surface dipoles, and the third part is due to interaction of the quadrupoles and dipoles. An order of magnitude analysis of these parts is carried out for different values of the flow Mach number, and the corresponding simplified expressions for the acoustic power are obtained.

Plate wave-scattering phenomena observed with pulse ESPI. **Alexander Schmidt** (Universität der Bundeswehr Hamburg, Germany), Rolf Lammering (Universität der Bundeswehr Hamburg, Germany) GA/CT1958/012

The experiments presented are part of investigations which focus on the assessment of capabilities of the *Electronic Speckle Interferometry* (ESPI) for general damage and flaw detection in structural health monitoring (SHM) and nondestructive testing (NDT).

The employed double-pulse ESPI system allows for non-contact measurements of spatially large fields of out-of-plane displacements with a resolution at least in the order of the laser wavelength. It is especially suited for measurements of transient processes or vibrations and is therefore highly unsusceptible to environmental interferences.

As test specimens, several $1000 \times 1000 \times 5mm$ steel plates are chosen with artificial flaws of different sizes, depths, and orientations. These flaws are not visible at the surface observed. The plate waves are excited by time harmonic bursts from piezo-transducers or by impact.

Experimental results will be shown, namely phase diagrams and displacement fields which are obtained from postprocessing procedures. These results include information about the location and the size of the flaws and allow for an assessment of the ESPI technique with respect to SHM and NDT. The propagation of surface waves in thin plates and the scattering phenomena with several configurations of artificial flaws are considered as first steps toward the intended later use of specific Lamb-wave modes with ESPI for SHM and NDT.

Acoustic scattering by a thin cylindrical screen with Dirichlet and impedance boundary conditions on opposite sides of the screen.
Pavel Krutitskii (Keldysh Institute of Applied Mathematics RAS, Russian Federation), Valentina Kolybasova (Lomonosov Moscow State University, Russian Federation) GA/CT2632/012

A problem on scattering acoustic waves by a thin cylindrical screen is studied. In doing so, the Dirichlet condition is specified on one side of the screen, while the impedance boundary condition is specified on the other side of the screen. The solution of the problem is subject to the radiating condition at infinity and to the propagative Helmholtz equation

$$\Delta u + k^2 u = 0, \quad k = \operatorname{Re} k > 0.$$

By using the potential theory the scattering problem is reduced to a system of singular integral equations with additional conditions. By regularization and subsequent transformations, this system is reduced to a vector Fredholm equation of the second kind and index zero. It is proved that the obtained vector Fredholm equation is uniquely solvable. Therefore the integral representation for a solution of the original scattering problem is obtained. The computational methods for finding the numerical solution are discussed.

Acoustic simulations with higher order finite and infinite elements.
Otto von Estorff (TU Hamburg–Harburg, Germany), Jan Biermann (TU Hamburg–Harburg, Germany), Steffen Petersen (TU Hamburg–Harburg, Germany) GA/CT2893/012

In recent years, the need of numerically solving the Helmholtz equation in the mid and high frequency range constantly increased. However, the efficiency of the numerical treatment of those problems is derogated by two facts: First, the numerical solution suffers from the so-called pollution effect, which gives rise to either very high element resolutions or to p-FEM concepts. Second, the resulting systems of equations are usually very large and call for the usage of iterative solution procedures, such as Krylov subspace methods. With increasing wave numbers, however, the deterioration of the spectral properties of the resulting system matrices affects the convergence and stability of those iterative solvers.
Generally, it is known that if higher order elements are used, the choice of the polynomial approximation function space is influencing the eigenvalue distribution of the resulting matrices and therewith the solution efficiency. In the present contribution the influence of different types of polynomial basis functions on the efficiency and stability of interior as well as of exterior acoustic simulations is analyzed. The investigations will show that a proper choice for the polynomial shape approximation may significantly increase the performance of Krylov subspace methods. In particular, the efficiency of higher order finite and infinite elements based on a Bernstein polynomial shape approximation and the corresponding iterative solution strategies are assessed. Moreover, practically relevant numerical examples including the sound radiation from rolling tires will show the efficiency of these 'Bernstein elements'.

Analytical modelling of active vibro-acoustic control.
Stefan Ringwelski (Universität Magdeburg, Germany) GA/CT3975/012

In recent years acoustic noise reduction has become an important concern in many industrial applications. Noise reduction increases the comfort of a system and reduces the noise radiation into the environment. The usual way to reduce the vibration and noise level of a structure is the application of additional damping materials. An alternative way for decreasing the vibration and noise emission results through the use of smart structures. A smart structure consists of a passive mechanical structure and integrated active materials, which in connection with an associated controller minimize unwanted vibration and sound radiation.

Usually the design process of a smart structure is based on numerical methods. In order to verify numerical techniques, experimental and analytical reference solutions are required. For this purposes the present paper derives an analytical reference solution for an active vibroacoustic system. The analytical model consists of a cavity coupled with a rectangular plate, which contains piezoelectric patch actuators and sensors. Based on the classical Kirchhoff equation, the transverse motion of the vibrating rectangular plate is described. The sound propagation in the cavity is characterized by the acoustic inhomogeneous wave equation written in terms of the velocity potential. The actuating forces of the piezoelectric patches due to control are expressed by equivalent bending moments. The control loop is closed by different feedback algorithms like velocity feedback control and optimal linear quadratic control.

For solving the coupled equations, a modal approach is used, in which the unknown field variable, i.e. velocity potential and the plate displacement, are approximated as a sum of the uncoupled acoustic modes and structural modes. The analytical solution is compared with numerical simulations as well as experimental data from measurements.

Modelling wave-propagation phenomena in time domain using the symmetric Galerkin BEM and convolution quadrature method.
Lars Kielhorn Kielhorn (Universität Graz, Austria), Martin Schanz (TU Graz, Austria) GA/CT2703/012

The understanding and modelling of wave propagation phenomena are of great importance in many engineering applications. Those phenomena can be effectively analyzed with the Boundary Element Method (BEM), especially in large or unbounded media. Nowadays in engineering, the spatial discretization of the underlying time-dependent Boundary Integral Equations (BIEs) is mostly done via the Collocation method. For the time discretization the Convolution Quadrature Method (CQM) proposed by Lubich is considered. This time stepping procedure is based only on the fundamental solutions in Laplace domain and, therefore, can also deal with problems where the fundamental solutions are not available in time domain.

The present work focuses on time-dependent BIEs arising from elastodynamics and the scalar wave equation. Again, the chosen time stepping procedure is the CQM but instead using a collocation method, a variational formulation is used resulting in a Galerkin based method in space. As will be shown numerically, this kind of discretization leads to an improvement of the numerical stability with respect to the time discretization.

In almost all engineering applications, mixed boundary value problems have to be solved, i.e., not only pure Dirichlet or pure Neumann problems are under considerations. Therefore, additionally to the 1st BIE also the 2nd BIE is used. Evaluating the 1st BIE on the Dirichlet part of the boundary and the 2nd BIE on the Neumann part of the boundary leads, finally, to a skew-symmetric linear system of equations, which may has better solution properties than those systems obtained by standard collocation methods.

After a short discussion of some necessary implementation details, both methods, the proposed Galerkin approach using the 1st and the 2nd integral equation and the more common Collocation approach using only the 1st integral equation, are compared with respect to the spatial and temporal discretization.

On the automated generation of reduced-order models in flexible multibody dynamics. **Jörg Fehr** (ITM, University of Stuttgart, Germany), Michael Lehner (Universität Stuttgart, Germany), Peter Eberhard (Universität Stuttgart, Germany) GA/CT1962/012

An important issue in the field of flexible multibody dynamics is the reduction of the flexible body's degrees of freedom. In this regard, a classical method is modal reduction. However, as the spatial character of the load acting on the body is not taken into account, convergence can be very slow. To improve convergence, the eigenvectors are often supplemented with additional assumed modes, e.g, static modes or frequency response modes. However, the choice of the proper set of basis vectors, consisting of eigenmodes and assumed modes, is a crucial task that requires much experience and insight into the specific problem. By the use of Gramian matrix based reduction techniques the distribution of the loads is taken into account *a priori*. Furthermore, an energy interpretation of the reduction procedure and error bounds in the frequency domain are available. In this work a frequency weighted second order Gramian matrix is defined that allows to generate a very accurate approximation of the flexible body's transfer function in a predefined range of the spectrum. Also, the stability properties of the original system are preserved. Hence, using this method only the load distribution, the frequency range of interest and a measure for the desired accuracy has to be provided. For diagonalizable models the second order Gramian matrix can be calculated analytically. However, appropriate approximation schemes have to be developed for large scale models. Here, we introduce such methods and discuss the convergence properties and suitable stopping criteria. The goal of the work is to provide a fully automated reduction process for flexible substructures in multibody systems. A numerical example demonstrates the approximation capability of the proposed technique in the frequency and time domain.

An Euler-solver for the acoustic far-field prediction of compressible jet flow. **Felix Keiderling** (ETH Zürich, Switzerland), Dominik Obrist (ETH Zürich, Switzerland), Sebastian Müller (ETH Zürich, Switzerland), Leonhard Kleiser (ETH Zürich, Switzerland) GA/CT2442/012

We report on a high-accuracy Euler solver developed for far-field jet noise prediction. The code is embedded in a framework of a Direct Numerical Simulation (DNS) / Large-Eddy Simulation (LES) code [1] providing the time-dependent, noise-generating flow field and the acoustic near-field.

The motivation for this development is twofold: First, we would like to efficiently and accurately predict jet noise not only in the acoustic near-field but also in the far-field region which is subject of most experimental investigations, as well as of interest to most practical applications. Second, we want to investigate the operative range of a previously developed analytical acoustic far-field solver, the SLM (Spectral Lighthill method), which is based on Lighthill's acoustic analogy [2].

The Euler solver employs the conservative formulation of the governing equations in generalized coordinates (ξ, η, ζ) that are mapped to a cylindrical frame of reference (r, θ, z). The set of equations is discretized using the same numerical components as the DNS/LES code, i.e., a highly accurate spatial discretization (with spectral-like resolution properties of $6th$ to $10th$ order compact-finite differences in the radial and streamwise directions and a Fourier spectral method in the azimuthal direction) combined with a fourth-order Runge-Kutta scheme in time that is optimized with respect to its dispersion and dissipation properties [3]. Numerical stability is ensured by employing the ADM-RT (relaxation-term) subgrid-scale closure developed within our group.

Details of the computational scheme will be presented. Results of the validation will be shown along with a comparison between predictions of the Euler solver and the SLM for analytical test cases.

Dynamisches Positionieren eines schwimmenden Körpers. **Marc-André Pick** (TU Hamburg-Harburg, Germany), Edwin Kreuzer (TU Hamburg-Harburg, Germany), Jörg Wagner (Universität Stuttgart, Germany) GA/CT1501/013

Numerische Bifurkationsuntersuchungen haben gezeigt, dass das Kentern von Schiffen durch eine Sequenz von Verzweigungen in der Dynamik des Systems "Schiff im Seegang" beschrieben werden kann. Um die Analyse zu beschleunigen, soll das verwendete und weltweit anerkannte nichtlineare Modell zur Beschreibung der dreidimensionalen Schiffsbewegung einschliesslich der Fluid-Struktur-Wechselwirkung durch reduziert werden. Zur Validierung der Modellreduktion ist es nötig, reproduzierbare Versuche mit einem schwimmenden Testkörper einfacher Geometrie unter genau definierten Bedingungen wiederholt durchzuführen. Zu diesem Zweck wurde ein dynamisch positionierbarer Schwimmkörper entwickelt, mit dem diese Forderungen im Wellenkanal des Institutes erfüllt werden können. Dabei ist es möglich, in einem frei zur Welle wählbaren Winkel die Antwort des Körpers auf die anregenden Wellen zu messen. Der Schwimmkörper ist mit sechs Aktoren (Waterjets) ausgestattet, die Schub in jeweils eine Richtung liefern. Es lassen sich damit die drei Freiheitsgrade ohne hydrostatische Rückstellkraft (Vorwärts-, Drift- und Gierbewegung) ausgleichen. Die Bestimmung von Position und Lage des Körpers wird durch ein integriertes Messsystem erreicht, das aus einer Stereo-CCD-Kamera und einer inertialen Messeinheit, die Beschleunigungen und Winkelgeschwindigkeiten bezüglich der körperfesten Achsen misst, besteht. Über ein erweitertes Kalman-Filter werden die beiden Messsysteme miteinander kombiniert, indem die Drift der Inertialmessung (Abtastperiode 5ms) durch Vergleich mit der durch die Kamera gemessenen Position (Abtastperiode 100ms) kompensiert wird. Damit werden langzeitstabile Messungen mit hoher Dynamik durchgeführt, die dem Regler als Rückführung dienen, und die für weitere Analysen aufgezeichnet werden.

Optimal design of a 2 DOF parallel robot. **Sergiu-Dan Stan** (Universitatea Tehnicã Cluj-Napoca, Romania) GA/CT92/013

The aim of this paper is to show the usefulness of the multicriteria approach to optimize the parallel robots. Variations of the kinematic performances index remain not constant throughout workspace. The potential of parallel robots is only then efficient exploited when their structure is optimal dimensioned from geometric point of view. So, their performances depend very strong on their geometry. Thus, optimization of the geometric parameters or optimal dimensioning has become an important issue for improving the parallel robots performances. Aiming to deal at the same time with multiple criteria in optimal design of parallel robots, we have developed a multiobjective genetic algorithm (MOGA) using concepts of Pareto optimality and niching techniques. Here, intended to show the advantages of using the MOGA, we applied it to a multicriteria optimization problem of 2 dof parallel robot. Genetic algorithms (GA) are so far generally the best and most robust kind of evolutionary algorithms. A GA has a number of advantages. It can quickly scan a vast solution set. Bad proposals do not affect the end solution negatively as they are simply discarded. The obtained results have shown that the use of MOGA in such kind of optimization problem enhances the quality of the optimization outcome, providing a better and more realistic support for the decision maker.

Force control of a fluidic-muscle-driven parallel platform. **Mahendra Dhanu Singh** (Universität Duisburg-Essen, Germany), Kusnadi Liem (Universität Duisburg-Essen, Germany), Rüdiger Neumann (Festo AG & Co. KG, Germany), Andres Kecskemethy (Universität Duisburg-Essen, Germany) GA/CT2255/013

In this paper a force control scheme for a parallel platform consisting of six fluidic-muscle actuator legs of type RRPS is presented. The objective of the control algorithm is to emulate arbitrary variable 6×6 stiffness properties at the end effector, such as needed for example to physically simulate soft tissue for component-in.the.loop testing. Fluidic muscles are well suited as actuators in robotics, since they have a high power/weight ratio, long durability and slip-stick-free motion. On the other hand, fluidic muscles require that the gas model as well as the rubber nonlinearities are included in the control scheme. Moreover, the control law for the gas flow in the proportional directional control valve in 3/3-way function needs to be taken into account. The present paper describes the basic dynamic models as well as testbed results for the existing fluidic-muscle parallel platform "HexaSpine", here each leg is equipped with a force sensor, a pressure sensor and a magnetostrictive position encoder respectively. The control scheme for the platform comprises six control loops for the six operated actuators with a model based force control each. It is shown that the aforementioned control scheme leads to a rapid stiffness simulation. As an application, the device will be employed in fields of biomechanics for physical simulation of cervical-spine motion, as well as in general environments requiring soft tissue physical simulation.

A method for determining control inputs for prescribed accelerations of the end-effector of an industrial robot. **Martin Tändl** (Universität Duisburg-Essen, Germany), Andres Kecskemethy (Universität Duisburg-Essen, Germany) GA/CT2721/013

Described in this paper is an approach for generating control inputs for an industrial Kuka robot such that it produces prescribed linear acceleration time histories for a given point of the end-effector. The method takes into account the workspace limits, and uses the internal interpolation cycle of the robot controller to generate the corresponding trajectories that will produce the prescribed accelerations. The PID parameters of the internal interpolation are identified from test measurements. The control scheme consists in producing time-varying values for the desired angle values of the interpolation algorithm, making the changes as the algorithm proceeds and thus generating smooth trajectories. The resulting acceleration of these trajectories is compared to the prescribed accelerations, and an optimization procedure is run such as to determine the required time-histories of the desired angles for the interpolation algorithm such that both accelerations match. The approach is demonstrated for the example of a 500kg payload Kuka robot that is aimed at producing given motions as a physical motion simulator (e. g. for cars or complex working machines). It is shown that the desired accelerations can be generated accurately and with high repeatability, making the approach suitable for example for simulating car rollover tests.

The Hide-Skeldon-Acheson dynamo revisited. **Irene Moroz** (University of Oxford, UK) GA/CT4375/013

Hide et al (1996) introduced a nonlinear system of three coupled ordinary differential equations to model a self-exciting Faraday disk homopolar dynamo. A very small selection of its possible behaviours was presented in that paper. Subsequent studies have extended the system to incorporate the effects of a nonlinear motor, an external battery and magnetic field, the coupling of two or more identical dynamos together, amongst other things. In this talk we return to the original model with a view to performing a more extensive analysis of the Hide et al (1996) dynamo. For the first time we present bifurcation transition diagrams, so that the two examples of chaotic dynamo action shown as figure 9 in that paper can now be placed into context. We exhibit the coexistence of multiple attractors and also identify the lowest order unstable periodic orbits pertaining to some specific cases.

Vibration elimination in cable-stayed footbridges and bridges. **Wojciech Pakos** (Wroclaw University, Poland), Zbigniew Wójcicki (Wroclaw University of Technology, Poland), Jacek Grosel (Wroclaw University, Poland) GA/CT3023/013

In this paper, the problems of eliminating vibration in cable stayed footbridges and bridges by dynamically steering the tension in cables during construction vibration are considered. A physical and a mathematical model of cable stayed footbridges and bridges has been formulated. A damping model has been selected on the basis of an analysis of vibrations due to periodic excitation. Standard computer software and the authorŠs own program, both leaning on Finite Element Method (FEM), have been used to analyze the eigenproblem and the forced vibration of bridges. On the basis of the formulated theory an efficient algorithm of forced vibration reduction analysis was established. The reduction is achieved by dynamically steering the tension in cables. A sensitivity analysis has been used. An example has been provided. The theory presented takes into account the new method in the elimination of vibration in cable stayed bridges and footbridges. It can therefore be applied to dynamic analysis of modern cable stayed bridges with typical structure systems.

Active control of working machines seat suspension aimed at health protection against vibration. **Igor Maciejewski** (Koszalin University of Technology, Poland) GA/CT3092/013

The paper presents the model and simulation of passive and active earth-moving machines seat suspension. The object of the simulation is the visco-elastic passive seat suspension with an air-spring, hydraulic shock-absorber and scissors guidance mechanism. Based on the measurements of the passive seat, the stiffness, damping coefficient and friction force is evaluated in this way, that the behavior of real seat suspension and model is nearly the same. Passive seat suspension amplifies the vibration amplitude at low frequency range of excitation signal (the resonance effect). The lowest resonance frequencies of human body parts occur for the internal organs of abdominal cavity (stomach: 2-3 Hz). In order to help the working machines operators against vibration, the active system with different control strategies is elaborated. Active system improves significantly the behavior of the seat suspension at low frequency excitation, with the most effectiveness obtained for the resonance frequency. The simulation is carried out using the excitations in accordance to ISO 7096 standard. As the results of the computer simulation, the power spectral densities of acceleration for a seat is presented in comparison with sample excitations on the earth-moving machines cabin floor. Additionally, the transmissibility functions for a passive suspension and the corresponding active suspension are shown.

Voltage-amplification transfer-function analysis of the operational amplifier in the negative-capacitance circuits for vibration control with piezo-ceramics. **Robert Oleskiewicz** (Koszalin University of Technology, Poland), Marcus Neubauer (Universität Hannover, Germany), Tomasz Krzyzynski (Koszalin University of Technology, Poland) GA/CT2787/013

Piezo elements due to their ability of converting mechanical energy into electrical energy and vice versa can be found in numerous mechanical vibration damping and absorbing applications. A desired effect may be customized by an external impedance shunt branch connected to the plates of the piezo element. The recent research shows that the negative capacitance connected in serial with the passive shunt significantly improves the damping and absorbing performance of such systems. Negative capacitance circuit is built up of an electronic impedance converter realized by the operational amplifier. Since the operational amplifiers are not the ideal elements, the performance of the proposed systems is limited, especially for small values of the electromechanical coupling coefficient of the piezoceramics. The main limitation, beside the maximum voltages and currents at which the operational amplifiers operate, comes from the finite gain of the circuit and the phase lag between the input and the output terminals. This effect causes instabilities and limits the operational area of the impedance converter. In the paper, the amplification transfer function of the non-ideal operational amplifier in the negative impedance converter is studied, and the necessary modification with the additional passive elements is proposed. The influence of the certain imperfections in the design, and its improvements are shown on the system consisting of the 1DOF mechanical oscillator, and a shunted piezo element.

Modeling of a vehicle seat suspension system with pneumatic spring and viscous dampers. **Sebastian Chamera** (Koszalin University of Technology, Poland), Igor Maciejewski (Koszalin University of Technology, Poland), Tomasz Krzyzynski (Koszalin University of Technology, Poland) GA/CT3035/013

The paper contains physical and mathematical model of the passive system of seat suspension, used in trucks and buses. The object of modeling is the Czech made serial produced seat. Spring force in this system is performed by air spring, whereas damping force is generated in two viscous dampers. Based on the experimental research of characteristic parts of the suspension system, the parameters of mathematical model are determined. Simulations and experiments are done by using white noise excitation in frequency range of 0-10 Hz, and two different excitations, according to ISO 7096. Both results of computer simulations and experiments are presented as power spectral density of acceleration courses, measured on seat, in comparison with courses measured on excitation platform in laboratory. Transmissibility of real system and its model are also presented in the paper. To estimate vibroisolation properties, SEAT (Seat Effective Amplitude Transmissibility) factor is determined, according to the standard, estimated at weighted values of frequencies. Given results enable further improvement of suspension system and better vibroisolation properties.

Method for evaluation of movement resistance in Scarper pipe conveyors. **Kazimierz Furmanik** (University of Science and Technology, Poland), Michal Pracik (Cracow University of Technology, Poland) GA/CT2163/013

Scarper pipe conveyors find more and more broad use in transportation of loose and powdery materials because this mode of material transport remains a cost-effective method. One can point disadvantages of these conveyors - a relatively large movement resistance inside the pipe, especially on vertical routes, and abrasive wear of chutes and chains. The state of art in designing of such conveyors is still not satisfactory. Rational process of designing needs a new approach to estimation of movement resistance, which will take into account basic parameters of conveyor construction and properties of transported materials. In the paper there is introduced a new method of determination of movement resistance and presented experimental verification basing on results of investigations carried out on a suitable stand up. Using the method one can perform a variety of calculations of the conveyor construction in order to find optimum values of its parameters that meet required capability, capacity and lower horsepower consumption. Analysis of theoretical and experimental investigation results related to the proposed method let formulate final conclusions.

Stability constraints in optimization of cracked columns subjected to compressive follower load. **Szymon Imielowski** (Institute of Fundamental Technological Research, Poland), Roman Bogacz (Institute of Fundamental Technological Research, Poland) GA/CT4250/013

Maximization of the critical force of cracked columns, subjected to generalized follower load is considered. In the modern mechanical structures the follower force can be caused; e.g., by systems of active control. The crack is assumed to be formed according to the opening and sliding modes and is modeled by localized loss of stiffness namely by elastic joint with possible rotational and shear deformation. The column is modeled by Bernoulli–Euler beam. The equation of motion for small harmonic vibration of are taken into consideration.

The crack localization and its stiffness which maximizes the critical load under the constraints of a constant total column mass and length and a constant column cross-sections are developed. The objective function $\lambda^*_{\mathrm{cr}} = \lambda^*_{\mathrm{cr}}(\Delta\alpha)$, where $\Delta\alpha$ stands for a set of design variables, is not defined explicitly. The optimization conditions, imposed in the frequency domain, are defined as limitations on variation of the shape of characteristic curves. The optimal point is defined as one that represents the state for which all pairs of eigencurves become double roots with the same value of critical forces. In the multimodal analysis the first six eigenfrequencies are considered.

An influence of the crack stiffnesses and its localization on the value of the critical force is presented. The localization of crack with the critical force of the system equal to $137.17\,\mathrm{EJ/L^2}$ is found.

Computing minimal optimization horizons for stabilizing unconstrained MPC schemes. **Lars Grüne** (Universität Bayreuth, Germany) GA/CT1544/013

In this talk we consider MPC schemes for nonlinear discrete time systems in arbitrary metric spaces. More precisely, we consider the MPC feedback law $F(x_0) := u_0$ obtained from the online solution of the finite horizon optimal control problem

$$\min_{u_0,\ldots,u_{N-1}} \sum_{j=0}^{N-1} \ell(x_j, u_j)$$

where x_j, $j = 0, 1, \ldots$, denotes the system trajectory for initial value x_0 and control sequence $u_0, \ldots, u_{N-1}$. If the system is exponentially controllable to the origin and the running cost $\ell(x, u)$ is a positive definite function in x, then it is well known that the resulting feedback F stabilizes the closed loop for sufficiently large (but in general unknown) optimization horizon N.

In this talk we assume null-controllability of $\ell(x_j, u_j)$ with prescribed bounds on the attraction rate and overshoot, and look for the minimal optimization horizon N^* for which asymptotic stability of the closed loop holds. Minimal here is to be understood in the sense that for any optimization horizon $N < N^*$ there exists a system which satisfies the assumed controllability property and is not stabilized by the MPC feedback law with this N.

We show that if the assumed controllability property is linear in the initial value (as, e.g., for exponential controllability or for finite time controllability with linear bound on the overshoot), then this problem can be formulated as a linear program whose complexity is independent on the dimension of the state space and on the degree of nonlinearity of the underlying dynamics. This linear program is of moderate complexity and can thus be solved by standard solvers. Based on the numerical findings from this procedure we are then able to conjecture on theoretical bounds for the optimal N^* depending on overshoot and attraction rates.

A min–max version of Dijkstra's algorithm with application to perturbed optimal control problems. **Marcus von Lossow** (Universität Bayreuth, Germany), Lars Grüne (Universität Bayreuth, Germany), Oliver Junge (TU München, Germany) GA/CT1757/013

Discrete time optimal control problems over an infinite horizon are studied for themselves or are obtained by a time-discretization of a continuous time control system. Perturbed systems of that kind are often used to describe mechanical or economic problems subject to external perturbations. On the other hand, the error caused by the numerical state-space-discretization of an unperturbed system can also be considered as a perturbation of the system.

In our talk we present a new method for solving this kind of problem. The method is based on a set oriented discretization of the state space in combination with a new algorithm for the computation of shortest paths in weighted directed hypergraphs. One of the fastest algorithms for shortest path problems, Dijkstra's algorithm, can be extended to a "min-max Dijkstra" algorithm. We will describe this algorithm and discuss suitable data structures and the corresponding computational complexity which increases only moderately using a suitable implementation. Furthermore we will give an outlook on how to use this approach to construct a suboptimal feedback to stabilize such control systems.

This new approach will be illustrated by a number of numerical examples.

Minimum-time optimal interception with terminal constraints. **Vasile Istratie** (National Institute for Aerospace Research, Romania) GA/CT2112/013

This work studies the interception laws for maneuvering targets with known trajectories in the of the three-dimensional in case minimum time optimal, while in Ref. 1 and 2, where this problem is solved for the minimum of fuel. Optimal interception problems are defined, which include constraints on final flight-path angles of the interceptor. The interceptor is moving at a constant velocity and can change its flight direction by applying bounded normal acceleration. The variational problem is of Mayer (or Lagrange) type, and the optimum control to be determined being angles acceleration direction The target is moving along an *a priori* known trajectory with known velocity. The coordinates describe the location of the interceptor and the target, respectively, relative to the origin of an arbitrary reference coordinate system. The problem is to find the angles acceleration direction - the optimal control input time history, so that the equations of the interceptor are satisfied and the performance index (the minimum time) is minimized while intercepting a target with a known trajectory. By means of the Legendre-Clebsch condition it is demonstrated that the formulated optimization problem is a maximum problem. The optimization problem is solved applying the PontriaghinŠs maximum principle, as well as in the problem from Ref. 1-3. So, the above defined problem of optimal control is transformed in a two point boundary problem. The nonlinear differential equations of the extremes where any kind of approximation was eliminated are precisely integrated by a numerical method, shooting, [4], [5]. Numerical examples that demonstrate the optimal trajectories are presented showing also the effect of the interceptor final flight-path angles on the interception characteristics.

A note on the numerical treatment of dynamical systems with friction. **Alexander Lünenschloß** (TU Darmstadt, Germany) GA/CT3175/013

The modeling of dynamical systems with friction leads to ODEs with discontinuous right-hand side. In this case the phase space contains manifolds where the directions of the crossing trajectories are discontinuous. In regions of these manifolds trajectories may point towards each other, and the solution stays on the manifold. This behavior is called sliding mode, but it is not covered by classical theory of ODEs. The regularization of the discontinuities leads to solutions that show undesired properties. A numerical computation based on Filippov's sliding-mode definition shows the desired behavior: In this case the time of a complete trajectory can be composed of intervals alternating classical solutions and sliding modes. These alternating intervals require different algorithms, and so does the transition between them. The given examples compare regularized and compound solutions.

Optimal singular control for systems involving parameters. **Mihai-Emilian Popescu** (ISMMA-Bucharest, Romania) GA/CT3143/013

What we shall take into consideration is represented by the problems of singular optimal control when the index of performance, the differential constraints and the final conditions contain parameters. What is determined is the trajectory of the neighboring extremal for the initial point perturbed at the constraints of the perturbed final manifold. The present study evaluates the variation of the command on the extremal. This one allows obtaining the second variation in the singular case. The sufficient conditions of minimum are a result of imposing the non-negativity of the second variation. The application made analyses the optimality of the singular control for a system in the class of affine differential systems.

A variational approach to optimal control problems for elastic body motions. **Georgy Kostin** (Institute for Problems in Mechanics RAS, Russian Federation), Vasily Saurin (Institute for Problems in Mechanics RAS, Russian Federation) GA/CT809/013

The initial-boundary problem for the linear theory of elasticity is considered. Based on the method of integrodifferential relations a new dynamical variational principle in which displacement, stress, and momentum functions are varied is proposed and discussed. To minimize the nonnegative functional under initial, boundary, and differential constraints arising in this approach a regular algorithm for approximation of the unknown functions is worked out. The algorithm gives us the possibility to estimate explicitly the local and integral quality of obtained numerical solutions. An effective numerical method for the optimization problems of controlled motions of elastic bodies with quadratic objective functionals is developed. As example, the 3D problems of optimal longitudinal motions of a rectilinear elastic prism with a quadratic cross section are considered for the terminal total mechanical energy to be minimized. The numerical results and their error estimates are presented and discussed.

Practical tracking with prescribed behaviour for electric drives. **Achim Ilchmann** (TU Ilmenau, Germany) GA/CT1819/013

We consider a two-mass flexible servo system with flexible connection between machine and load modelled, see for example [2], by

$$\dot{x}(t) = A\,x(t) + b\,u(t) + b_T\,\psi(\omega_2(t))\,, \qquad (1)$$

with

$$A = \begin{bmatrix} -d/J_2 & k/J_2 & d/J_2 \\ -1 & 0 & 1 \\ d/J_1 & -k/J_1 & -d/J_1 \end{bmatrix}, \quad b = \begin{pmatrix} 0 \\ 0 \\ 1/J_1 \end{pmatrix}, \quad b_T = \begin{pmatrix} -1/J_2 \\ 0 \\ 0 \end{pmatrix},$$

where the state vector $x = (\omega_2,\ \Delta\varphi,\ \omega_1)^T$ contains the speed of the load, the angle of twist between the drive and the load and the speed of the drive, $\psi\colon \mathbb{R} \to \mathbb{R}$ models the nonlinear friction force depending on ω_2 and is assumed to be bounded with unknown bound.

A prototypical example for the model is an electric drive. In industrial applications induction machines are used which are supplied by an AC-converter. Since the underlying current control loop is based on the speed of the drive, a sensor for ω_1 is indispensable. The controlled variable ω_2 is assumed to be measurable as well. These two variable allow for a reduction of the relative degree. Without measurement of the angle of twist no active damping can be provided by a PI-controller,

even if the plant is perfectly known [2]. Hence a sensor for $\Delta\varphi$ is import for good performance. In some applications position sensors are used such that the state $\Delta\varphi$ is computed very easily by a simple difference of the position of both masses. Thus we consider an output y so that the system $u \to y$ has relative degree one.

Next we show that the zero dynamics are asymptotically stable; this global result is an extension of local results[3].

Moreover, rewriting the system in an appropriate form it can be shown that it belongs to the class of systems that have been studied[1], so that *funnel control* is applicable. A funnel controller ensures that the error between the output of the system and a reference signal, $e = y - y_{\mathrm{ref}}$, evolves within a prespecified *funnel*. This controller is simple in its design, it is a sort of adaptive controller, not based on any identification mechanisms.

The theoretical results are underlined by experiments with a two-mass flexible servo system. The obtained results show, that the presented control strategy is appropriate for electrical drive systems in industrial applications.

An adaptive fuzzy controller for nonlinear systems with dead-zone. **Wallace Bessa** (Centro Federal de Educação Tecnológica, Brazil), Max Dutra (Universidade Federal do Rio de Janeiro, Brazil), Edwin Kreuzer (TU Hamburg–Harburg, Germany) GA/CT2777/013

The dead-zone nonlinearity is frequently encountered in many physical components of industrial control systems, especially those containing some very common actuators, such as hydraulic proportional valves and electric motors. Dead-zones are often poorly known and their characteristics may also vary with time. It was already observed that their presence can severely reduce control system performance and lead to limit cycles in the closed-loop system. Due to the possibility to express human experience in an algorithmic manner, fuzzy logic has been largely employed in the last decades to both control and identification of uncertain dynamical systems. In spite of the simplicity of this heuristic approach, in some situations a more rigorous mathematical treatment of the problem is required. Our aim is to present an adaptive fuzzy control scheme for nonlinear systems with unknown dead-zone. The stability properties of the closed-loop system will be proven using Lyapunov stability theory and Barbalat's lemma. Numerical results will be also presented in order to demonstrate the control system performance.

Cell-mapping methods for random dynamical systems. **Andreas Gaull** (TU Hamburg–Harburg, Germany), Edwin Kreuzer (TU Hamburg–Harburg, Germany) GA/CT1551/013

This contribution is concerned with the numerical study of the global behavior of dynamical systems subjected to stochastic perturbations. An extended version of the Cell Mapping method is employed as a numerical toolbox.

For deterministic systems, Cell Mapping represents an approximation of the Frobenius–Perron operator by a Galerkin method. This operator describes the evolution of densities under a given system transformation. We want to point out how this concept can be expanded to Random Dynamical Systems and specify a stochastic analog of the deterministic Frobenius–Perron operator. The method of Cell Mapping provides finite dimensional approximations of invariant densities and allows a characterization of attractors as well as the basins of attractions. At this juncture, investigation of the discretized Frobenius–Perron operator is based on the techniques from symbolic dynamics.

Optimal control of structure-variant rigid-body mechanical systems. **Kerim Yunt** (ETH Zürich, Switzerland) GA/CT1024/013

A measure differential inclusion (MDI) based modeling approach for rigid-body mechanical systems will be introduced, that can exhibit autonomous or controlled mode transitions, accompanied by discontinuities on velocity and acceleration level. The introduced framework will have the ability to model and control of hybrid mechanical systems with discontinuous transitions among different system modes. Modeling of rigid-body Lagrangian systems as LCP will be presented. The properties of the optimal control problem derive from the underlying modeling approach. The main issue in the optimal control of hybrid mechanical systems has been the blending of impact mechanics with impulsive optimal control. The discontinuities arising from impacts and stick-slip transitions are primarily contact phenomena, which conccure temporally and spatially. The spatial conccurence of discontinuity is due to the fact that discontinuities on velocity level (e.g. collisions) can occur along with discontinuities on acceleration level (e.g.stick-slip transitions). Temporal conccurence is caused by collision, shock and impact phenomena occuring at multiple locations of the system at the same time as well as stick-slip transitions. Recent research showed that such rigid-body systems can best be described by variational inequalities which lead to nonlinear and linear complementarity type of systems to be solved in order to obtain the accelerations/velocities and forces. In the modeling considered in this work, impulsive forces can arise autonomously, due to effects such as collisions or controlled/nonautonomously, due to actions such blocking some DOF. The hybrid optimal control requires the consideration of an uncommon concept of control, namely, controls of unbounded, impulsive and set-valued type.

Minimum integrated altitude control for the terminal bunt manoeuvre. **Subchan Subchan** (Cranfield University, UK) GA/CT3014/013

An optimal control problem of a generic cruise missile attacking a fixed target in minimum altitude along the trajectory is investigated. The missile must struck the target from above, subject to missile dynamics and path constraints. The generic shape of the optimal trajectory is: level flight, climbing, diving; this combination of the three flight phases is called the bunt manoeuvre. The numerical solution of optimal control problem is solved by combination of a direct method and an indirect method. A direct approach based on a collocation method is used to reveal the structure of the optimal solution which is composed of several arcs, each of which can be identified by the corresponding manoeuvre executed and constraints active. The direct approach produces approximate solutions for both states and co-states. The indirect approach is then employed to derive optimality conditions based on Pontryagin's Minimum Principle.

Generalized p-Galerkin time-integration schemes for durability mechanics and structural dynamics. **Detlef Kuhl** (Ruhr-Universität Bochum, Germany) GA/CT3558/013

The present paper is concerned with generalized discontinuous and continuous Galerkin time integration schemes of arbitrary polynomial degree (dG(p) and dG(p)) to single- and multifield structural mechanics. In particular, first order semidiscrete initial value problems associated with transport dominated computational durability analyses described by the non-linear vector differential equation $\mathbf{r}_i(\dot{\mathbf{u}}, \mathbf{u}) = \mathbf{r}(t)$ and second order semidiscrete initial value problems associated with computational structural dynamics $\mathbf{r}_i(\ddot{\mathbf{u}}, \dot{\mathbf{u}}, \mathbf{u}) = \mathbf{r}(t)$ are solved by this class of algorithms. Therefore, the discontinuous GALERKIN schemes proposed by [1,2] and the continuous GALERKIN schemes proposed by [3,4,5] are formulated within a generalized framework. This family of p-GALERKIN time integration schemes includes the numerically dissipative and energy conserving continuous Galerkin schemes as well as the discontinuous GALERKIN method for first and second order nonlinear problems as special cases. Studies of discontinuous and continuous GALERKIN schemes in the context of calcium leaching of cementitious materials shows the potential of this integration methods in the presence of non-smooth DIRICHLET boundary conditions, non-smooth initial conditions and moving dissolution fronts. Furthermore, the order of accuracy of dG(p)- and cG(p)-schemes can be controlled by the polynomial degree $\mathcal{O}(p)$ and $\mathcal{O}(p+1)$, respectively. The application of discontinuous GALERKIN schemes to non-linear structural dynamics illustrates the stable numerical solution, the dissipation of energy within the high frequency range of the structural response and the controllable higher order of accuracy $\mathcal{O}(2p+1)$. Depending on the damping parameter [5], $2p$th order accurate generalized continuous GALERKIN schemes cG(p) applied to HAMILTONian systems are characterized by the conservation or decay of total energy.

Model reduction for bilinear diffusion and diffusion–reaction systems. **Tobias Damm** (TU Kaiserslautern, Germany), Peter Benner (TU Chemnitz, Germany) GA/CT3071/013

Discretization of diffusion equations with Neumann-type boundary control or reaction-diffusion equations leads to large-scale bilinear control systems of the form

$$\dot{x} = Ax + \sum_{j=1}^{k} N_j x u_j + Bu\,, \quad \text{with} \quad y = Cx\,.$$

In some respects these systems still behave like linear systems. For instance, if A is stable, then the system defines a bounded input/output operator $G : L^2 \to L^2$ by setting $Gu = y$. Therefore, it is natural to look for an approximation of G by an input/output operator G_r of a lower dimensional system.

One simple, but easy to implement approach is to use the state-space projections obtained by balanced truncation (based on the Gramians) of the linear part of the system (with $N_j = 0$), and apply these projections to the bilinear system. A more advanced idea is to obtain the projections by balancing generalized Gramians of the bilinear system. For selected examples, we compare these approaches with respect to their computational complexity and the error $\|G_r - G\|$.

Constraints on the convergence behaviour of algorithms via reachable set analysis. **Jens Jordan** (Universität Würzburg, Germany) GA/CT2670/013

Many iterative algorithms can be interpreted as discrete-time control systems evolving on manifolds. Here, shift parameters act as control inputs. The Adherence structure of the reachable sets provides fundamental limitations on the possible convergence behaviour of the algorithm.

We analyse the reachable sets and their structure for a family of numerical algorithms, using geometric and algebraic tools. We apply our results on well-known numerical algorithms, such as Inverse Iteration and Richardson Iteration. In particular, we show necessary conditions for the existence of local convergent shift strategies and feedback laws.

Dynamics of open quantum systems. **Uwe Helmke** (Julius-Maximilians-Universität Würzburg, Germany), Gunther Dirr (Julius-Maximilians-Universität Würzburg, Germany), Indra Kurniawan (Universität Würzburg, Germany) GA/CT2181/013

The dynamics of open quantum systems is desribed by the Lindblad equation on positive-semidefinite Hermitian operators. As shown by Lindblad (1976) using functional analytic methods, the differential equation preserves the class of completely positive operators. In this talk we present an approach based on the theory of Lie semigroups to tackle this problem, in particular concerning preservation of positive semidefiniteness under the flow. We also discuss some problems concerning controllability of a two spin system.

Actuated conformation change in a chain of oscillators. **Philip Du Toit** (California Institute of Technology, USA) GA/CT2843/013

We study robustness and control in a system of coupled oscillators that exhibits two conformational states. Each conformation is robust against large random perturbations, yet the action of a small structured perturbation that excites resonances in the natural dynamics of the oscillator chain causes the chain to coherently and robustly undergo a conformation change from one state to the other. Therefore, the oscillator chain has the interesting property that it remains locked in a conformational state for large random perturbations, but global conformational change can be easily induced by the action of a small targeted control. Our motivation for studying this oscillator chain arises in the study of biopolymers that exhibit exactly this property. DNA, for instance, is well-known to be a stable biomolecule requiring temperatures in excess of $60°$C to induce melting or denaturalization of the DNA helix, yet specialized proteins such as helicase and polymerase are able to robustly unlock the DNA strands and induce melting so that the essential processes of DNA replication and transcrip-

tion can occur.

More specifically, we consider a class of biopolymers that can be modeled as a chain of pendula attached to a rigid backbone. The motion of each pendulum is governed by two interactions: each pendulum interacts with its nearest neighbor through a harmonic potential that models torsional coupling through the backbone, and secondly, each pendulum moves in a Morse potential that models the weaker Hydrogen bonding interaction between pendulum pairs on a complementary chain. We observe that the Morse potential establishes the robust states of conformation, and that small controls can induce conformation change by exciting resonances in the dynamics of the nearest neighbor coupling.

Further understanding of the conformation change is gained through a novel approximation that reduces the many degree of freedom system to a coarse $1\frac{1}{2}$ degree of freedom system in which the coarse variables retain precisely the interaction that describes the global conformation change. We demonstrate that the coarse model accurately captures statistics of the conformation change and the effect of various perturbations and controls.

Control algorithms using online simulation. **Radu Balan** (Universitatea Tehnicã Cluj-Napoca, Romania), Vistrian Maties (Universitatea Tehnicã Cluj-Napoca, Romania), Sergiu-Dan Stan (Universitatea Tehnicã Cluj-Napoca, Romania), Olimpiu Hancu (Universitatea Tehnicã Cluj-Napoca, Romania) GA/CT2177/013

Today, many industrial systems are still controlled by simple PID (proportional-integrative-derivative) algorithms, despite the better performances usually provided by systems developed following the modern control theory. This is probably not only due to the quite surprising efficacy of this simple control method, but also to the higher computational load and design effort required by most of the more sophisticated control techniques. PID controllers can be used to control a wide range of different processes, need only rough process models to be easily tuned and give pretty good set-point tracking performances. On the other hand it is clear that PID performances, although satisfactory, could be improved when dealing with highly nonlinear processes, or processes featuring unmodeled dynamics and external disturbances. The paper presents a control algorithm based on the on-line simulation of the future behavior of the control system, by using a few candidate control sequences. Then, using the rule based control, these simulations are used to obtain the ŚoptimalŠ control signal. The efficiency and applicability of the proposed algorithm are demonstrated through applications.

An elastic beam approach to predictive vehicle motion planning with low curvatures. **Karina Hirsch** (Universität Duisburg-Essen, Germany), Thorsten Brandt (Universität Duisburg-Essen, Germany) GA/CT1592/013

Vehicle guidance systems are among the latest automotive developments. Examples are automatic cruise control, lane departure warning and active lane keeping. However, the rapid development of environmental sensor systems such as radar, lidar and video technologies in combination with data fusion of the single sensor signals enables further applications as for example lane changing assistance, collision avoidance or even autonomous driving. For all of these functions, trajectories have to be planned and, depending on the application, to be communicated to the driver. Recently, methods originally developed in robotics as for example so-called elastic bands are adopted for road vehicle applications. However, vehicle dynamics are in general not considered in these approaches. Though, for road vehicles at high speeds drivability becomes an important issue: if the curvature of the planned trajectory is locally too high for the intended speed, the vehicle will start skidding. For this reason a new motion planning approach is proposed. The vehicle is guided along a virtual elastic beam, which is deflected by virtual potential fields generated by obstacles in the traffic space. In doing so, the elastic beam avoids obstacles and provides collision-free trajectories. In particular, the flexural stiffness of the beam can be chosen with respect to vehicle dynamics.

Integrated measurement system using accelerometers and gyros as peripheral sensors to estimate the motional state of an elastic beam. **Thorsten Örtel** (Universität Stuttgart, Germany), Jörg Wagner (Universität Stuttgart, Germany) GA/CT1746/013

Integrated navigation devices for vehicle guidance are the most common example of an integrated motional measurement system combining the signals from an inertial measurement unit (three accelerometers, three gyros) and a GPS receiver with a single antenna. Traditionally, the vehicle is assumed to be a single rigid body with six motional degrees of freedom to be determined. During periods of low vehicle dynamics the common integrated navigation systems show stability problems. Nevertheless, the stability of the system can be guaranteed by distributing sensors over the vehicle structure. However, in this case the rigid body assumption has to be expanded to take the distributed sensors and the flexibility of the structure into account.

Integrated systems in general are fusing different measuring signals by combining their benefits and blinding out their disadvantages. For instance, gyros and accelerometers are used to obtain reliable signals with a good time resolution. On the other hand, aiding sensors like radar units and strain gauges are known to be long-term accurate. Furthermore, the kernel of the integrated systems consists of an extended Kalman filter that estimates the motion state of the structure. Besides the sensor signals, the basis for the filter is an additional kinematical model of the structure which has to be developed individually.

The example of the motion of an elastic beam being considered here is meant to be an approach to obtain motional measurements of a wing of a large airplane during flight. By means of a modal approach, a kinematical model of the beam was developed. This paper will compare integrated systems utilising accelerometers as peripheral sensors with systems using gyros and systems with a combination of both peripheral sensor types. Based on simulation the paper shows this approach, different sensor configurations, and estimated motion results of an elastic beam.

Multimodel control approuch for electrohydraulic servo systems. **Olimpiu Hancu** (Universitatea Tehnicã Cluj-Napoca, Romania), Vistrian Maties (Universitatea Tehnicã Cluj-Napoca, Romania), Radu Balan (Universitatea Tehnicã Cluj-Napoca, Romania) GA/CT2760/013

The paper proposes a control design approach based on a multipoint linearization method for linear electro-hydraulic servo systems. The nonlinear model of servo system is linearised around of operational points and Matlab environment is used to adjust the points distribution based on error estimation. These models are used to design an optimal controller which online modifies the feedback control parameters. Simulation and experimental results are provided to show the effectiveness of approach.

Control and stability analysis of a turbocharged diesel engine using singular-perturbation methods. **Hannes Seyrkammer** (Universität Linz, Austria), Kurt Schlacher (Universität Linz, Austria) GA/CT2390/013

This contribution is concerned with the application of a nonlinear control and stability analysis for diesel engines equipped with a variable geometry turbocharger (VGT) and an exhaust gas recirculation (EGR) valve, using singular perturbation methods. The recirculation of exhaust gas from the outtake manifold to the intake manifold is an effective way to reduce the concentration of nitrogen oxides in the exhaust gas. Using a VGT, a fast transient response time at low engine speeds and high engine power without turbine overspeeding at high engine speeds is possible. The system to be controlled is described by the following simple scheme: air enters the system through the compressor and is led to the intake manifold. Mixed with the recirculated gas it is pumped into the engine. Inside, fuel is injected and the combustion takes place. The produced exhaust gas flows into the exhaust manifold. A part is recirculated to the intake manifold, the rest flows through the turbine, transferring energy to the compressor. For the controller design a simplified mathematical representation is given by a set of three ordinary differential equations. These equations can be split into two parts with slow and fast transient response. The goal of the controller is to achieve desired values of the input manifold pressure and the compressor massflow, both given by the motor management system for a given point of operation. To guarantee that the deflection of the desired and actual signals converge to zero, the controller is equipped with two slow integral states. The equations for the closed loop system can be written as a nonlinear standard singular perturbated system. The asymptotic stability is shown with the choice of Lyapunov functions for the reduced and the boundary layer system such that the necessary interconnection conditions are also satisfied. The performance of the controller is demonstrated by simulation results also in combination with a more detailed simulation model.

Controlled piezoelectric actuators in machine tools. **Christian Rudolf** (Universität Karlsruhe (TH), Germany), J Wauer (Universität Karlsruhe (TH), Germany) GA/CT1467/013

In machine tools of parallel structure with two or three translatory degrees of freedom rotatory degrees of freedom are kinematically locked. However, due to geometric faults, such as installation errors or different geometries due to production tolerances, those machine tools suddenly exhibit a full three dimensional behavior resulting in stresses within the structure and leading to deflections of the tool center point. Thus, the quality of the workpiece is reduced.
To compensate these errors an adaptronic strut which can be implemented within such a machine tool has been developed. The strut comprises a piezoelectric sensor-actuator unit for the force controlled correction of those static and quasistatic deflections since piezoelectric elements are advantageous due to their high accuracy and the small installation space required.
Here, a control design for the compensation is presented. After considering a single adaptronic strut as a standalone system with external loads representing constraint forces, the strut is implemented within the machine tool. Then, the effect of the controlled strut on the operating behavior of the machine tool is investigated.

Inversion-based trajectory planning for the heat equation with temperature-dependent parameters and radiation boundary conditions. **Tilman Utz** (Universität des Saarlandes, Germany), Thomas Meurer (Universität des Saarlandes, Germany), Daniel Wild (Universität des Saarlandes, Germany), Andreas Kugi (TU Wien, Austria) GA/CT3453/013

In hot-rolling mills, metal slabs are heated in pusher-type reheating furnaces from the ambient temperature to a final temperature required for the hot-rolling process; see e.g., [1,2]. To meet the metallurgical demands, it is required to reach certain temperature profiles within the slabs along pre-planned temporal paths within a given time interval. Thereby, radiation represents the primary mode of heat transfer within the furnace such that energy is exchanged between the furnace and the slab along the slab surface.

Modelling of the temperature distribution within a slab leads to a description in terms of the heat equation with temperature-dependent heat capacity, mass density and thermal conductivity. Furthermore, in good accordance with physical evidence, it suffices to consider only heat conduction in the vertical direction (i.e., over the height of the slab), which renders the model spatially 1-dimensional[2].

For the solution of the trajectory planning problem, in this contribution an inversion-based approach is applied, which is based on the appropriate semi-discretization of the governing nonlinear heat equation with radiation boundary conditions using Finite Differences with respect to the spatial coordinate. For this, it is assumed that the furnace temperatures above and below the slab can be utilized as the control inputs. Based on the semi-discrete approximation, it is shown that the temperature and its gradient at the core of the slab represent so-called flat outputs of the system[3]. This allows us to parametrize the temperatures at the discrete locations as well as the boundary inputs in terms of the flat outputs and their time-derivatives. Hence, prescribing appropriate trajectories for the flat outputs directly yields the control inputs which are necessary to track the core temperature and its gradient along the prescribed path in open-loop. Furthermore, the parametrizations of the spatially discrete temperatures can be utilized to ensure that the temperature gradient along the slab height remains in an admissible range in order to fulfill the metallurgical requirements on the heating process.

Control of port-Hamiltonian systems by interconnection and energy shaping via generation of Casimir functions. **Alessandro Macchelli** (Università di Bologna, Italy), Arjan van der Schaft (University of Groningen, Institute of Mathamatics, The Netherlands), Claudio Melchiorri (Università di Bologna, Italy) GA/MT4238/014

In this talk, an overview on the control by interconnection and energy shaping via Casimir generation for port Hamiltonian systems is presented. This control methodology has its origins in the Energy-Casimir method according to which stability can be proved by using in Lyapunov analysis next to system Hamiltonian other conserved quantities. In the control by interconnection, the controller structure is chosen in order to properly introduce such conserved quantities (Casimir functions) and shape the energy of the system such that a minimum in the desired equilibrium configuration can be introduced. The basic results on the stabilization of finite dimensional systems are summarized and then generalized in order to deal with the infinite dimensional case.

Modeling, simulation and control of a doubly-fed induction machine. **Carles Batlle Arnau** (Universitat Politècnica de Catalunya, Spain), Enric Fossas Colet (Universitat Politècnica de Catalunya, Spain), Arnau Dòria Cerezo (Universitat Politècnica de Catalunya, Spain) GA/MT4240/014

This presentation deals with a complex multidomain system, including the control objectives specification, modeling, control design, simulation, experimental setup assembling and experimental validation stages. The system under study is an energy storage system whose main components are a flywheel, a doubly-fed induction machine and a back-to-back electronic power converter. Along with the study of this specific system, a review is presented of the major techniques employed, namely port Hamiltonian system theory and interconnection and damping assignment-passivity based control, and some original theoretical improvements of the basic control technique are also obtained.

On geometric dynamics of rigid multi-body systems. **Stefano Stramigioli** (Universiteit Twente, The Netherlands) GA/MT4246/014

Standard methods to model multibody systems are aimed at systems with configuration space isomorphic to $\mathfrak{R}^n$. This limitation leads to singularities and other artifacts in case the configuration space has a different topology, for example in the case of ball joints or a free-floating mechanism. The presentation discusses an extension to classical methods to allow for a very general class of joints, that includes all with a Lie group structure, as well as nonholonomic joints. The model equations are derived using the Boltzmann-Hamel equations and have the same structure and complexity as in the standard results, but do not suffer from singularities. Furthermore, they avoid implicit formulations (both for holonomic and nonholonomic joints) and can be directly implemented in simulation software.

On the interconnection structures of discretized port-Hamiltonian systems. **Bernhard Maschke** (Université Claude Bernard Lyon I, France) GA/MT4345/014

Port Hamiltonian systems are an extension of infinite-dimensional Hamiltonian systems which allow to model open physical systems having some exchange of energy with their environment through the boundary of their spatial domain . They are defined on a Dirac structure, called Stokes-Dirac structure, which is an extension of the Poisson bracket associated with the differential operator arising in systems of conservation laws .It has been shown that such Stokes-Dirac structures not only arise in models of conservative systems (in the sense of Thermodynamics) such as vibrating strings or isentropic flows, but also in models of irreversible systems such as diffusion processes or heat conduction . For the purpose of numerical simulation or control, a mixed-finite element method has been developed that preserves the port-Hamiltonian structure of the system . However this method has been applied for systems defined on 1-dimensional spatial domain. In this paper we shall suggest some generalization of these result to higher-dimensional spatial domains by the use of Whitney forms defined on a primary mesh and its dual mesh.

Controllability of the double-bracket flow. **Uwe Helmke** (Julius-Maximilians-Universität Würzburg, Germany), Gunther Dirr (Julius-Maximilians-Universität Würzburg, Germany) GA/MT4943/014

We investigate the controllability properties of Brockett's isospectral double bracket flow on selfadjoint projection operators. Generic conditions for accessibility of the flow are proven, using results on the classification of transitive Lie group actions on Grassmann and Lagrange-Grassmann manifolds. Our results imply corresponding accessibility results for the dynamic matrix Riccati equation with multiplicative controls.

Time-variant Hamiltonian control systems: a covariant approach. **Markus Schöberl** (Universität Linz, Austria) GA/MT4952/014

In this contribution we present an intrinsic description of time variant Hamiltonian control systems. This formulation is based on the splitting of the state bundle and the use of appropriate covariant derivatives, which guarantees that the structure of the equations is invariant with respect to time variant coordinate transformations. The analysis of the change of the Hamiltonian along solutions of the system leads to some new perspectives in the time variant setting, which can be analyzed using geometric methods. This is important from the control theoretic point of view, since this is linked closely to the stability analysis. The trajectory tracking problem for time invariant Hamiltonian control systems can be formulated using the developed theory, since the use of displacement or error coordinates fits perfectly into this covariant setting. Furthermore, if the nontrivial state bundle connection can be absorbed in a modified Hamiltonian, the control task to stabilize the tracking error can be handled by standard methods.

Observability of polynomial and analytic nonlinear systems. **Bernd Tibken** (Bergische Universität Wuppertal, Germany) GA/MT5032/014

In recent years the derivation of effective and computationally verifiable criteria for observability of nonlinear systems has gained some interest. In this contribution the observability is defined in a global way using differential geometric conditions it is shown how the well known local results can be derived and the limitations of this approach are clarified. By specializing to polynomial systems some recent results from real algebraic geometry will be applied in order to derive global conditions for observability. It is shown with several examples that these conditions can be tested effectively. The extension of this approach to the important subclass of Pfaffian analytic systems is presented and illustrated with examples. The main tools which are used are differential geometry and algebraic geometry and especially classical ideal theory. The presentation ends with conclusions and an outlook.

Solidifying-crystal solute flow control through thermo-electric–magnetic interaction. **Koulis Pericleous** (University of Greenwich, UK), Georgi Djambazov (University of Greenwich, UK), Andrew Kao (University of Greenwich, UK), Vaughan Voller (University of Minnesota, USA) GA/CT2039/014

Often metals and alloys solidify in the presence of electromagnetic fields that have marked effects on microstructure and finally properties. The process that creates these microstructures is not well understood and therefore possible benefits gained by a deliberate control of the interaction are not realized. This driver motivates this study, where the solutal flow surrounding a growing dendritic crystal is manipulated through the action of an external magnetic field. The magnetic field interacts with the thermoelectric Seebeck currents present along the solid/liquid interface to generate an electromagnetic Lorentz force. This in turn creates a micro-convection field that can alter the morphology and growth rate of the dendrite. The thermoelectric currents are naturally present along the interface, due to temperature differences between the tip and the root of each dendrite branch where solid and liquid Seebeck strengths differ. To simulate this effect, equiaxed dendrites are grown from grains in a supercooled alloy melt, using an enthalpy front-tracking approach due to Voller. VollerŠs microstructure code is embedded into the Finite Volume CFD package PHYSICA, where in addition to enthalpy, equations are solved for velocity and electromagnetic field. The resulting micro-convection has a marked effect on single and multiple dendrite growth patterns.

Thermo-electric currents in weld pools. **Adrian Lange** (Frauenhofer Institut IWS, Germany), Eckhard Beyer (Frauenhofer Institut IWS, Germany) GA/CT3105/014

In order to achieve higher welding speeds and a better quality of the weld seam, external static magnetic fields are tested for laser beam welding. Experiments with fine grained steels and aluminium alloys show a reduction of so called humping effect, an improvement of the top seam quality, and an influence on the cross section of the seam [1,2]. These phenomena depend on the orientation of the magnetic field. To explain that dependence, the existence of thermoelectrical currents was proposed in [1,2]. The interaction of that proposed currents with the external field shall generate a Lorentz force distribution in the weld pool which may be the reason for the observed phenomena.

Based on the Onsager relation for the thermoelectrical current density and the appropriate boundary conditions in the case of laser beam welding, thermoelectrical currents can be determined analytically [3]. Results for iron and aluminium are presented in a approximative two-dimensional geometry. For iron the assumed current density distribution was confirmed qualitatively. For aluminium the calculated strength of the current is in agreement with the experimental measurements. Since measurements for the values of the thermoelectrical (Seebeck) coefficient of both materials are spare, different hypothetical material sets are tested and discussed.

Subcritical instability of liquid metal channel flow in the presence of a spanwise magnetic field. **Thomas Boeck** (TU Ilmenau, Germany), Dmitry Krasnov (TU Ilmenau, Germany), Maurice Rossi (Université Pierre et Marie Curie, France), Oleg Zikanov (University of Michigan, Dearborn, USA) GA/CT2318/014

The stabilizing effect of a homogeneous magnetic field on the subcritial instability and transition to turbulence in plane Poiseuille flow of an electrically conducting fluid is studied using hydrodynamic stability theory and direct numerical simulations. The magnetic field is oriented in the spanwise direction.

The transition to turbulence depends on the transient growth of non-modal linear perturbations, which are characterized by their stream- and spanwise wavenumbers. The kinetic energy of the velocity perturbations is used to quantify the energy amplification.

In the non-magnetic case, the most amplified perturbations are purely streamwise rolls. As the Lorentz force tends to suppress motion in the spanwise direction, the most amplified perturbations change from streamwise rolls to oblique rolls as the magnetic field increases. For sufficiently strong fields, motion in the spanwise direction is strongly damped and only the two-dimensional Tollmien-Schlichting waves aligned with the magnetic field provide significant transient amplification. The consequences of this damping effect on the transition to turbulence are studied through direct simulations.

TB and DK are supported by the Deutsche Forschungsgemeinschaft (grant Bo1668/2-2), and OZ by the Dept. of Energy (grant DE FG02 03ER46062). The cooperation between TU Ilmenau and UM Dearborn is supported by DAAD and NSF (grant OISE 0338713).

Electromagnetic flow control of glass melts: theoretical contribution. **Cornelia Giessler** (TU Ilmenau, Germany), Andre Thess (TU Ilmenau, Germany) GA/CT1820/014

The goal of our investigations is to show the possibility to control efficiently glass melt flow with Lorentz forces. We report an analytical model to study the main features of the flow and results of coupled 3D-numerical simulations. The flow control with Lorentz forces is a new way to control the flow rate and temperature in forehearth and feeder systems and increase homogenisation in crucibles and melters without contact.
The analytical model mainly consists of the energy equation and the Stokes equation including buoyancy, friction and Lorentz force. The characteristic features of glass melt such as high viscosity and the strong non-linear temperature dependence of the electrical conductivity and viscosity are taken into account. To drive the glass melt with Lorentz forces we impose crossed external current density and external magnetic field density. Altogether we obtain a complicated interplay between the variation of the material parameter, the heat equation and the Stokes equation. One of the most interesting and intriguing effects is bifurcation in the flow characteristics once the Lorentz force and the change of material parameters go through a certain critical value.
The 3D numerical model describes a crucible containing glass melt and two electrodes being inserted into the melt. Thermal convection develops as result of the density differences. With an additional external magnetic field Lorentz force is generated between the electrodes. We show parameter studies for the power input, magnetic field density and the two possible orientations of the Lorentz force. Furthermore, we compare calculations with constant and temperature-dependent electrical conductivity and reveal the importance of correct implementation of this material parameter.
Overall, the model shows that it is possible to control the glass melt flow using externally applied electromagnetic forces efficiently. The results obtained are compared with experimental results [1].

Asymptotic methods for spherically-symmetric MHD α^2-dynamos. **Uwe Günther** (FZ Dresden–Rossendorf, Germany), Oleg Kirillov (Lomonosov Moscow State University, Russian Federation) GA/CT3043/014

We consider two models of spherically-symmetric MHD α^2-dynamos; one with idealized boundary conditions (BCs); and one with physically realistic BCs. As it has been shown in our previous work, the eigenvalues λ of a model with idealized BCs and constant $\alpha-$profile α_0 are linear functions of α_0 and form a mesh in the $(\alpha_0, \Re\lambda)-$plane. The nodes of the spectral mesh correspond to double-degenerate eigenvalues of algebraic and geometric multiplicity 2 (diabolical points). It was found that perturbations of the constant $\alpha-$profile lead to a resonant unfolding of the diabolical points with selection rules of the resonant unfolding defined by the Fourier coefficients of the perturbations. In the present contribution we present new exact results on the spectrum of the model with physically realistic BCs and constant α. For non-degenerate (simple) eigenvalues perturbation gradients are found at any particular α_0. We present a detailed study of the spectral behavior of the α^2-dynamo operator over a family of homotopic deformations of the BCs between idealized ones and physically realistic ones. Furthermore, we demonstrate that although the spectral singularities are lifted, a memory about their locations remains deeply imprinted in the homotopic family of the spectral deformations due to a hidden underlying invariance.

GA/CTS4818/14: Optimal control and design.

Organiser: Roland Griesse (RICAM Linz, Austria)
Co-organiser: Michael Hinze (Universität Hamburg, Germany)
Co-organiser: Gunter Gerbeth (Forschungszentrum Dresden–Rossendorf, Germany)

Optimal control of radiative transport. **René Pinnau** (TU Kaiserslautern, Germany) GA/CT3663/014

A tracking-type optimal control problem for the radiative transfer equation is studied. Necessary and sufficient optimality conditions are derived. Numerical methods for the model equation and its adjoint are presented. Computational results based on a steepest descent method underline the feasibility of our approach.

Optimal experimental design for flow problems. **Thomas Carraro** (Universität Karlsruhe, Germany) GA/CT2047/014

The theory and practice of optimal design of experiments is well known in several areas of engineering. The scope of this optimization technique is the reduction of the uncertainty in the information obtained by experiments. This is attained by an optimal choice of the experimental conditions. We propose a numerical method for optimal experimental design in the context of flow problems assuming a discretization by means of the finite element method.

Optimisation of an entire design chain in aerodynamics. **Andrea Walther** (TU Dresden, Germany), Nicolas Gauger (HU Berlin & DLR Braunschweig, Germany), Carsten Moldenhauer (TU Dresden, Germany) GA/CT1054/014

For optimising the properties of an air foil, we consider the following design chain consisting of four steps: The computation the geometry of the air foil for a given Hicks-Henne parametrisation, the evaluation of the difference of this air foil with respect to a given static geometry, the corresponding deformation of the given grid around the air foil and the computation of the drag using a special version of the flow solver TAU. To apply a calculus-based optimisation method, one has to differentiate the whole design chain with respect to the given parametrisation. We present and analyse first results for a gradient-based approach. Subsequently, we will discuss alternative methods to handle the substantial start-up calculation that results from the entire design chain. This yields different optimisation approaches aiming at a one-shot method.

Stability control in CFD by shape optimization. **Frank Strauss** (Universität Karlsruhe, Germany) GA/CT2409/014

We focus on problems of optimal control and hydrodynamic stability appearing in computational fluid dynamics. In that context we consider shape optimization problems with adequate objective functions subject to eigenvalue constraints. The eigenvalue state equation is given by the Navier-Stokes eigenvalue problem. Analytical issues focusing on existence results for the optimization problem as well as numerical aspects are addressed. Our study encompasses in particular the development of adequate numerical schemes. The complexity of the underlying problems leads to large highly nonlinear problems which are solved by means of techniques relying on high performance computing. Special attention is paid to the parallelization of the numerical methods developed in that framework. Various examples are presented including the design optimization of a racing yacht for the America's Cup.

On pump modular system for automated adjustment and control for axial piston pumps. **Calin Vaida** (Universitatea Tehnicã Cluj-Napoca, Romania), Liviu Ioan Vaida (Universitatea Tehnicã Cluj-Napoca, Romania), Doina Liana Pisla (Universitatea Tehnicã Cluj-Napoca, Romania), Adrian Pisla (Technical University Cluj-Napoca, Romania), Tiberiu Itul (Technical University Cluj-Napoca, Romania), Lucian Nascutiu (Universitatea Tehnicã Cluj-Napoca, Romania) GA/CT1681/014

Axial piston pumps are the most widely used pumps in hydraulic actuation systems. Their technical characteristics make them the best option for most applications starting from industrial machine tools, up to mobile equipments. Thus, the optimization of their functional parameters and their control within the system is of great importance. The paper presents the working principles of the electro-hydraulic adjustment systems for axial piston pumps with variable displacement. Further on, it is described the construction of a modular measuring and control head (developed entirely by the authors) mounted directly on the pump and ensures the achievement of any type of control: flow, pressure, power or their combinations. The measuring head is mounted on the output port of the pump, thus imposing no constructive modifications on the pump. Finally, the authors will present the testing stand and the experimental results obtained during the functioning of a pump equipped with this system under a flow control regime, pointing out the possibility of automation of complex technological processes, using a process computer or a programmable logic controller.

GA/CTS4814/14: Flow control.

Organiser: Michael Hinze (Universität Hamburg, Germany)

Mathematical methods in MHD flow control. **Roland Griesse** (RICAM Linz, Austria) GA/CT1697/014

Magnetohydrodynamics, or MHD, deals with the mutual interaction of electrically conducting fluids and magnetic fields. In particular, the magnetic fields interact with the electric currents in the fluid and exert a Lorentz force. This feature renders it so phenomenally attractive for exploitation especially in processes involving liquid metals, and in crystal growth.

The tayloring of currents and magnetic fields offers the possibility to drive the fluid in a desired way, e.g., in order to enhance mixing or to achieve flow damping. These goals can be formulated in terms of objective functions, which lead to optimal control problems. The emphasis in this presentation is on mathematical methods for the numerical solution of incompressible MHD optimal control problems.

Memory-efficient implementation of optimal-control problems for the Navier–Stokes equations. **Julia Sternberg** (Universität Hamburg, Germany), Michael Hinze (Universität Hamburg, Germany) GA/CT1000/014

Derivative-based solution algorithms for optimal control problems of the time dependent Navier-Stokes equations require multiple solutions of backward-in-time adjoint systems. Since these adjoint systems depend on the velocity, and thus on forward information, the storage requirement for such solution algorithms is very large.

We propose stable and memory efficient checkpointing techniques for evaluating gradients and Hessian×increment, and present numerical test which demonstrate that huge memory savings are achieved by our approach while the increase in runtime is moderate.

Finally, we discuss some possible future developments.

Optimal control of the free boundary in a two-phase Stefan problem with flow driven by convection. **Michael Hinze** (Universität Hamburg, Germany), Stefan Ziegenbalg (TU Dresden, Germany) GA/CT1018/014

We present an optimal control approach for the solidification process of a melt in a container. The process is described by a two phase Stefan problem including flow driven by convection and Lorentz forces. The free boundary (interface between the two phases) is modelled as a graph.

We control the evolution of the free boundary using the temperature on the container wall and/or the Lorentz forces. The control goal consists in tracking a prescribed evolution of the free boundary. We achieve this goal by minimizing a appropriate cost functional. The resulting minimization problem is solved numerically by a steepest descent method with step size control, where the gradient of the cost functional is expressed in terms of the adjoint variables.

Optimization of compressors in gas networks. **Michael Herty** (TU Kaiserslautern, Germany) GA/CT1045/014

We are interested in optimization issues arising in the context of gas flow in pipeline networks. Here, the dynamics of the flow inside the gas pipes is described by the isothermal Euler equations, i.e. a nonlinear hyperbolic partial differential equation. In physical networks compressor stations are introduced reduce the pressure loss due to wall friction. We present a model for a compressor and discuss optimization of the compressor load with respect to the dynamics governed by the isothermal Euler equations. We present analytical as well as numerical results.

Economical heat transfer. **Szpakowska Szpakowska** (Koszalin University of Technology, Poland) GA/CT3132/014

Heat transfer occurs in all situations involving objects of different temperatures. This paper is devoted to convective heat transfer and accompanying methods of its intensification. If the process could be intensified without any energy outlays, i.e. without the use of energy-consuming elements (fans, blowers), considerable economic benefits could be achieved. These could be employed not only in the industry but also in ordinary households. Nearly all technologies practically used in metallurgical, power, chemical or food industries require the provision or consumption of considerable quantities of heat.Intensification is effected by increasing airflow speed, usually by means of fans requiring a drive system, which entails considerable energy outlays. A number of design solutions of heat exchangers use the phenomenon of convective heat transfer. Heat exchangers of this type do not incorporate any devices producing fluid motion. In addition to that, they are easy to operate, durable and reliable.

GA/CTS4819/14: Ferro fluids.

Organiser: Stefan Odenbach (TU Dresden, Germany)

Free-surface phenomena and flow in ferrofluids. **Reinhard Richter** (Universität Bayreuth, Germany), Christian Gollwitzer (Universität Bayreuth, Germany), Christopher Groh (Universität Bayreuth, Germany), Holger Knieling (Universität Bayreuth, Germany) GA/CT2770/014

The Rosensweig- or normal field instability [1] is one of the most striking phenomena of ferrofluids. Above a threshold B_c of the vertically oriented magnetic induction B_z the initially flat surface gives way to a stationary pattern of liquid crests. Despite its 'advanced age' of 40 years the nonlinear properties of the instability became only recently gaugeable, thanks to use of radioscopy [2].

We measure the amplitude and shape of the hexagonal pattern versus the magnetic induction and compare the results [4] with analytical [3] and numerical treatments of the instability. Moreover we uncover localized states (*ferrosolitons*) in the bistable regime [5], which are recovered by the finite element method [6]. For higher inductions the hexagons are followed by squares via a *proteretic* transition [7]. By adding a horizontal field component B_x the symmetry of the pattern can be broken [3]. For fixed $B_x > 0$ and increasing B_z liquid ridges appear supercritically [8], which are replaced by stretched hexagons via a subcritical bifurcation at higher inductions. Contrary, fixing B_z and increasing B_x shows for the first time a coexistence of two different hexagonal pattern. The instability is measured as well for inverse ferrofluids. Due to their apparent yield stress [9] an elastic energy contribution becomes important, resulting in a shift of B_c to higher values, which is confirmed by theory [10]. Eventually the static surface structures are moved by means of a rotating magnetic field, a *magnetic pump* [11].

Maximal growth rate at the Rosensweig instability: theory, experiment, and numerics. **Holger Knieling** (Universität Bayreuth, Germany), Adrian Lange (Frauenhofer Institut IWS, Germany), Gunar Matthies (Ruhr-Universität Bochum, Germany), Ingo Rehberg (Universität Bayreuth, Germany), Reinhard Richter (Universität Bayreuth, Germany) GA/CT3062/014

Instabilities in magnetic fluids (MF) have had a long history with the most eye-catching phenomenon being the normal field or Rosensweig instability [1]. When a critical value B_c of the vertical magnetic induction is surpassed, static liquid peaks arranged in a hexagonal pattern are rising on the free surface of the fluid.

A linear description of the Rosensweig instability is amenable in theory, but restricted to small amplitudes. In experiments they can be observed only for a very short time during the increase of the pattern of ridges, which bifurcate supercritically. Thus a new pulse technique has been developed and applied [2,3].

The ground state of a pattern forming system is subjected to small disturbances in order to study its stability. It is assumed that in the linear state of the pattern forming process the wave number with the largest growth rate will prevail. That growth rate is the last remaining quantity which has not been measured and compared to the theoretical results. This contribution is devoted to fill this gap and presents theoretical, experimental, and numerical results for the maximal growth rate for two different MFs. Primarily results show that the experimental and numerical data agree satisfyingly whereas the theoretical data show a sizeable disagreement. The reasons for the latter will be discussed.

Structure formation and phase behaviour in ferro-fluid monolayers: theory and computer simulations. **Juan Jose Cerda Pino** (Universität Frankfurt, Germany), Christian Holm (Universität Frankfurt, Germany), Sofia Kantorovich (Urals State University, Russian Federation) GA/CT1998/014

Ferrofluid particles are known to self-assemble into a variety of magnetic equilibrium structures which depend on several factors such as: system geometry, magnetic interactions, particle polidispersity, presence or absence of external fields, etc. The phase behaviour and microstructure of ferrofluid systems in reduced dimensions is not necessarilly equivalent to that of 3D systems. In order to investigate the peculiarities brought by the 2D geometry into the aggregation processes in ferrofluids, a combination of density functional theory, and molecular dynamics (MD) simulations is presented. Long-range dipolar interactions in our monolayer simulations are computed using a recently developed dipolar-P3M-layer correction algorithm. In comparison to the traditional Ewald sum methods, this approach allows to handle larger systems. The mircrostructure formation and the phase behaviour of monodisperse and bidisperse ferrofluid monolayers are studied thoroughly. The effects induced by the presence of external fields applied to the ferrofluid monolayers are also studied in detail. An extensive comparison of the theoretical, and computational results to the experimental results from *in situ* cryogenic tansmission electron microscopy [1] will be also presented.

[1] M. Klokkenburg, R. Dullens, W. Kegel, B. Erné, and A. Philipse; *PRL* **96**, 037203, (2006); *PRL* **97**, 185702, (2006).

Locomotion based on the control of the shape of magnetic fluid surfaces and of magnetizable media. **Klaus Zimmermann** (TU Ilmenau, Germany), Vera Naletova (Moscow State University, Russian Federation), Igor Zeidis (TU Ilmenau, Germany), Vladimir Turkov (Moscow State University, Russian Federation), Valter Böhm (TU Ilmenau, Germany), Emil Kolev (TU Ilmenau, Germany) GA/CT1940/014

The realization of locomotion based on the deformation of a free surface of a magnetic fluid layer in a traveling magnetic field is studied. It is known that the traveling magnetic field can create a flux in the fluid layers. The theory of the flow of layers of magnetizable fluids in a traveling magnetic field is considered. A plane flow of an incompressible viscous magnetic fluid layer on a horizontal surface in a nonuniform magnetic field, a plane two-layers flow of incompressible viscous magnetic fluids between two parallel solid planes in a magnetic field, a flow of an incompressible viscous magnetic fluid layer on a cylinder in a nonuniform magnetic field, and other problems are considered. Experiments for the estimation of the forces arising on a surface of a magnetic fluid under the action of a controlled magnetic field are conducted. It is theoretically and experimentally shown that there is a possibility of creating a travelling wave on the surface of the fluid layer by means of a magnetic field. The deformation and the motion of a body made by a magnetizable polymer in an alternating magnetic

field are experimentally studied. The cylindrical body (worm) which is located in a cylindrical tube is considered. It is found that there is an undulation of the worm in a periodic traveling magnetic field of special structure and the worm moves along the tube. In our experiments the maximal worm velocity is 20cm/s. The calculations of the deformation and the velocity of the worm in an applied magnetic field are done. It is shown that the theoretical results agree with the experiments. Calculation of the worm deformation is done using ANSYS. These effects can be used in designing autonomous mobile robots without a hard cover. Such robots can be employed in clinical practice and biological investigations.

Rheological properties of ferrofluids. **Loredana Mirela Pop** (TU Dresden, Germany), Stefan Odenbach (TU Dresden, Germany) GA/CT2924/010

Due to the possibility to change the physical properties of ferrofluids (i.e., long-term stable colloidal suspensions of nanometer-sized magnetic particles in appropriate carrier liquids) by means of moderate magnetic fields, they can be used to solve a wide variety of technical problems. The usage of magnetically controlled fluids requests not only a good knowledge about the basic properties of ferrofluids but also about their behaviour in the presence of magnetic fields. Thus, effects like, for example, field induced changes of fluids viscosity are subject of actual research activities. Experiments made for different ferrofluids under shear flow have shown that an increase of magnetic field strength yields an increase of the fluids viscosity, the so called magnetoviscous effect, while increasing shear rate leads to a decrease of the viscosity. Combining rheological with SANS investigations, a strong connection between structure formation in ferrofluids under the influence of a magnetic field and their macroscopical behaviour has been established. Based on this knowledge and in order to reach the requirements demanded by applications, new fluids, exhibiting stronger dependence of their properties on magnetic fields, have been developed.

While the previous rheological experiments could been successfully performed using a cone plate rheometer, for the investigation of the highly-concentrated ferrofluid samples new problems arise. Thus, for example, even at very low magnetic field strengths spikes are formed on the free surface of the fluid limiting the range of magnetic field strengths for the investigations. To overcome this problem, a specially designed capillary viscometer has been developed. Additionally, this viscometer allows the variation of the direction of magnetic field relative to the fluid flow. This will enable a comparison of the experimental data to the results of a new macroscopical theory made by M. Liu [Muller et all., 2006 J. Phys. 18].

Rheological investigations of ferrofluids with a shear stress controlled rheometer. **Hamid Shahnazian** (TU Dresden, Germany), Stefan Odenbach (TU Dresden, Germany) GA/CT2997/014

Ferrofluids are superparamagnetic suspensions of nanosized magnetic particles with a mean diameter of about 10 nm in appropriate carrier liquids, like water, oil or organic solvents. The magnetic particles are covered with a polymer shell to keep them stable against sedimentation and to prevent agglomeration. One of the most promising properties of ferrofluids is the possibility to significantly influence their behavior by moderate magnetic fields. This allows to use magnetic forces for the control of properties and flow of these liquids, giving rise to numerous technical and biomedical applications. Recent rheological experiments, performed on ferrofluids, have shown strong change of the viscosity (magnetoviscous effect) and the appearance of viscoelastic effects caused by applied magnetic fields. These effects can be explained with chain and structure formation due to interparticle interaction in the presence of a magnetic field. Additionally, with increase of shear rate structures are broken and the relative change of viscosity decreases. This effect is known as shear thinning. In order to explain the effects different theoretical approaches have been developed, which vary in the basic modelling of the fluid and its behaviour. A point in which the predictions of the models differ is the question of the appearance and field dependence of a yield stress in ferrofluids. For the investigations concerning yield stress a shear stress controlled rheometer for ferrofluids has been designed. The results show a dependence of the yield stress on magnetic field strength for different kind of ferrofluids and magnetorheological fluids. Variation of geometry - cone/plate or plate/plate - and distance of the walls in plate/plate geometry of the shear cell give information on the microscopic size of the structures formed by the magnetic particles and its dependence on field strength as well as interparticle interaction.

Parametric modulation of thermal and thermomagnetic convection in magnetic fluids. **Harald Engler** (TU Dresden, Germany), Stefan Odenbach (TU Dresden, Germany) GA/CT2998/014

Magnetic fluids, also called ferrofluids, are suspensions of magnetic monodomain particles with an average diameter of 10 nm in an appropriate carrier liquid such as oil, water or others. The possibility to control the properties of ferrofluids by means of a magnetic field opens an interesting research field in fluid mechanics as well as technical applications in industry.
This work considers heat and mass transfer phenomena especially convection phenomena in a horizontal fluid layer in ferrofluids in the presence of an external time modulated magnetic field. The driving force in thermal convection depends on the temperature difference and geometric boundary. Furthermore, for such a thermal convection system exists a critical temperature difference for which the transfer of heat changes from diffusion to convective flow. In general the driving force in such a convection experiment is constant in time. In the frame of this work the behaviour of the critical temperature in a convection system with periodically modulated driving force has been investigated. Former theoretical investigations predict that the critical temperature of thermal convection depends on the frequency of the driving force. However the experimental realisation of a situation where thermal convection is subjected to a time variable driving force fails due to immense technical problems. For the investigations of the behaviour of the critical temperature the circumstance is used that the driving force in ferrofluids depends on the temperature difference, geometric boundary and additionally on magnetic body forces. This kind of convection is called thermomagnetic convection. The magnetic force in ferrofluids can thus be modulated in time by a modulation of magnetoic field strength leading to the required time dependent driving force. The experimental setup designed for the investigation of thermomagnetic convection under time varying magnetic driving forces as well as first results on the shift of the stability of the system will be presented.

Numerical study of liquid-metal flow in a rectangular duct under the influence of a heterogenous magnetic field. **Egbert Zienicke** (TU Ilmenau, Germany), Evgeny Votyakov (TU Ilmenau, Germany) GA/CT2897/014

We simulated numerically the laminar flow in the geometry and the magnetic field of the experimental channel used by O. Andreev, Y. Kolesnikov, A. Thess, Phys. Fluids **18**, 065108 (2006). This provides detailed information about the electric potential distribution for the laminar regime (numerical simulation) and in the turbulent regime as well (experiment). As follows from comparison of simulated and experimental results, the flow under the magnet is determined by the interaction parameter $N = Ha^2/Re$ representing the ratio between magnetic force, determined by the Hartmann number Ha, and inertial force, determined by the Reynolds number Re. We compared two variants: (i) (Re, N)=(2000,18.6) (experiment), (400,20.25) (simulation), and (ii) (Re, N) =(4000,9.3) (experiment), (400,9) (simulation) and found an excellent agreement for the numerical and experimental distributions of the electric potential. This is true despite of the fact that the experimental inflow is turbulent while that in the simulation is laminar. As a special feature of the electric potential distribution local extrema under the magnets are observed, as well experimentally as numerically. They are shown to vanish, if the interaction parameter falls below a critical value. Another interesting new detail found in our numerical calculations is the appearance of helical paths of the electric current. Using a simplified magnetic field without span-wise dependence, we show that important physical features of the considered problem are sensitive to small variations in the spatial structure of the magnetic field: the local extrema of the electric potential and also the helical current paths dissappear when the simplified magnetic field is used. The structure of the three dimensional velocity field is also investigated, in particular, a swirling flow is found in the corners of the duct caused by Hartmann layer destruction behind the magnets.

Experiment on MHD turbulence at low magnetic Reynolds number. **Rico Klein** (TU Ilmenau, Germany), Alban Pothérat (TU Ilmenau, Germany) GA/CT2952/014

The work presents an experimental set-up of a scientific experiment concerning the 2D /3D MHD-turbulence transition mechanism in a cubic box, filled with the liquid metal alloy GaInSn and under an imposed constant magnetic field. We discuss the basic construction of our turbulence-box as well as we present first measurement results concerning the 2D/3D transition in MHD turbulence.Basically our box is designed as a modular system, consisting of a polyamid coated cubic brazen frame (inner side length 100mm, electrically insulated) with the respective side plates. On the particular sides of the cubic frame, perpendicular to the magnetic field direction, we install also varnish coated Copper-plates with integrated cards. These cards contain the flow generating mechanism by means of a constant electric current forcing over 100 uniform arranged Copper-electrodes, as well as the high number of 392 electric potential probes, connected to a single ended amplifier system.By real time measurements of the electric potential distribution on both Ha-walls, everyone with the same arrangement and number of 196 electric potential probes, we are able to determine the velocity profile and their high frequency fluctuations as well as we can check the 2D/3D transition, depending on the amount of the injected constant electric current and the magnetic field strength. To check the principal functionality of the experimental set-up and especially the precision of our signal processing system we perform an experiment in smaller scales. The small scale experiment consists of a closed cylindrical box (diameter d= 40 mm), filled with the liquid metall GaInSn (hight h = 5 mm), imposed under a strong magnetic field. The flow is generated by constant electric current forcing over two electrodes and the velocity profiles are measured by 56 electric potential probes on both Ha-walls.We present first results concerning the measurement precision(1 microVolt)and some characteristics of the flow.

GA/CTS4815/14: Flow and magnetic fields.

Electromagnetic flow control in weakly conducting fluids. **Tom Weier** (Forschungszentrum Dresden–Rossendorf, Germany), Christian Cierpka (Forschungszentrum Dresden–Rossendorf, Germany), Victor Shatrov (Forschungszentrum Dresden–Rossendorf, Germany), Gerd Mutschke (Forschungszentrum Dresden–Rossendorf, Germany), Gunter Gerbeth (Forschungszentrum Dresden–Rossendorf, Germany) GA/CT1719/014

Electromagnetic (i.e., Lorentz) forces can be used to control the flow of conducting fluids. This holds true even if the electrical conductivity is only weak, as in the case of electrolytes like sea-water.

The applications of streamwise, wall parallel Lorentz forces to generic flow configurations will be exemplified with experimental data from flat plate boundary layers and separated flows around cylinders and hydrofoils. These results demonstrate the ability of stationary Lorentz forces to change the velocity profile in boundary layers and thereby to improve their stability properties, as well as to completely suppress separation. Time dependent Lorentz forces are used to mitigate the lift loss and drag increase of hydrofoils caused by flow separation. In this case, the versatility of Lorentz force actuators allows for detailed experimental investigations especially of the effects of excitation frequency and wave form.

Finally, the impact of the low conductivity on the energy balance of Lorentz force actuators is discussed.

Control of a boundary layer separation. **Vaclav Uruba** (Czech Academy of Sciences, Czech Republic), Lukas Popelka (Czech Academy of Sciences, Czech Republic), Martin Knob (Czech Academy of Sciences, Czech Republic) GA/CT1921/014

Process of a flat-plate boundary layer separation is controlled using a synthetic jet. The boundary layer is subjected to adverse pressure gradient. Synthetic jet is located in the wall, oriented perpendicularly to the flow, the piezoceramic actuator is used. Dynamics of the separation process as well as the synthetic jet / cross flow interaction is studied experimentally using Time Resolved PIV technique.

Experimental results on unsteady boundary layer separation and control mechanism are to be presented. The proper orthogonal decomposition (POD) and bi-orthogonal decomposition (BOD) techniques are involved to study both topological and temporal aspects of the phenomenon. Influence of excitation parameters, namely the synthetic jet position, frequency and its intensity, on control process is to be studied qualitatively as well.

The experimental results will serve as a database to built a simplified mathematical model of the phenomenon.

Numerical simulations of a cylinder wake under a strong axial magnetic field . **Vincent Dousset** (TU Ilmenau, Germany), Alban Pothérat (TU Ilmenau, Germany) GA/CT2962/014

The study deals with the flow past a circular cylinder in a high magnetic field. The magnetic field is imposed along the cylinder axis. The quasi-2D flow model from Sommeria and Moreau (1982) is used. Finite-volume based computations are achieved to simulate the flow for six values of the magnetic field ($0 < B < 1.35T$) and $\mathrm{Re} < 6000$. In the MHD simulations, four successive flow regimes are found. The introduction of the magnetic field delays the apparition of the flow regimes. Few differences are noticed between the hydrodynamic case and the MHD cases concerning the steady flow regime. Concerning the MHD cases, scaling laws in $\mathrm{Re}/\mathrm{Ha}^{\alpha}$ were systematically found in terms of base pressure and drag coefficients, Strouhal number and length of the recirculation regions. Finally, the size of the boundary layer which surrounds the recirculation regions in the steady flow regime is proved to be of the order of magnitude of the characteristic length of the parallel layers.

Work done in collaboration with Alban Pothérat from the Technical University of Ilmenau.

On magnetohydrodynamic drag reduction and flow control behind a body. **Gunter Gerbeth** (Forschungszentrum Dresden–Rossendorf, Germany), Victor Shatrov (Forschungszentrum Dresden–Rossendorf, Germany) GA/CT2167/014

In the first part we present results of direct numerical simulations on turbulent channel flow drag reduction using electromagnetic forces. The Lorentz force is created by the interaction of a permanent magnetic field and an electric current from electrodes placed on the bottom wall surface. We consider the two cases of a spanwise oscillating force and a streamwise steady force. In the second part the flow behind an electromagnetically self-moved sphere is considered for which a drag reduction is found. Results on the linear and nonlinear flow stability will be provided.

Structure of the wake of a magnetic obstacle. **Evgeny Votyakov** (TU Ilmenau, Germany), Egbert Zienicke (TU Ilmenau, Germany), Andre Thess (TU Ilmenau, Germany) GA/CT1842/014

We describe vortices appearing in a liquid metal which flows through and around a magnetic obstacle; i.e., a region where an inhomogeneous magnetic field is applied. This region is featured by the braking Lorentz force due to an interaction of the electrically conducting flow and external magnetic field. Depending on the relationship between viscous, Lorentz and inertial forces, the liquid metal flow shows three different regimes: (1) no vortices, when viscous force prevails at small Lorentz force, (2) one pair of *magnetohydrodynamic* vortices between the magnetic poles, when Lorentz force is high and inertia small, and (3) three pairs, namely, magnetohydrodynamic as above, *connecting*, and *attached* vortices, when Lorentz and inertial forces are high. The attached vortices are similar those which are in usual hydrodynamics in the stagnant region of the flow past a solid cylinder. Since the magnetohydrodynamic and attached vortices are co-rotated, such a motion requires contrrotation between them and this originates connecting vortices. When the inertia force is even higher than in the case (3), then attached vortices develop a vortex breakdown. All types of vortices are found in 3D numerical simulation and confirmed by a physical experiment. Global stability diagrams are discussed.

Electromagnetic flow measurement. **Andre Thess** (TU Ilmenau, Germany) GA/CT1702/014

Electromagnetic fields can be used in a variety of ways to measure the velocity of electrically conducting fluids. Whereas inductive flowmeters provide a convenient and commercially successful means to measure velocities in low temperature fluids like beverages, chemicals, and wastewater, flow measurement in high temperature melts has remained a largely unsurmounted challenge up to now. The present communication will discuss various non-contact methods for flow measurements at high temperature. It will particularly focus on a method, called Lorentz force velocimetry, which consists in measuring the force on a magnet system that interacts with a flow. The advantages and drawbacks of the method will be discussed and an outline of potential applications will be given.

2D and 3D transition of forced MHD turbulence. **Vitali Dymkou** (TU Ilmenau, Germany), Alban Pothérat (TU Ilmenau, Germany) GA/CT3041/014

We consider the incompressible Navier–Stokes equations under an externally imposed magnetic field. The Navier-Stokes equations are taken on the 3D periodic box. The aim is to show the mechanisms which govern the transition between two-dimensional (2D) and three-dimensional (3D) turbulence. We present numerical simulation results using standard pseudo-spectral methods.

Free-surface instabilities during electromagnetic shaping of liquid metals. **Christian Karcher** (TU Ilmenau, Germany), Vaclav Kocourek (TU Ilmenau, Germany) GA/CT2179/014

Electromagnetic shaping of free surfaces of liquid metals is a well-known EPM technology used in a couple of metallurgic processes like cold crucible melting, semi-levitation, and electromagnetic slit sealing, among others. However, the stability of such free surfaces is the most important problem and stability control is crucial for success. Within this context we investigate experimentally the stability behavior of liquid metal free surfaces submitted to a high-frequency magnetic field. The magnetic field is generated by a ring-like inductor fed by an alternating electrical current of high frequency of up to 300 kHz. In this case, the induced Lorentz forces act as an electromagnetic pressure directly on the free surface of the liquid metal. We consider two experimental model configurations: (i) Liquid metal drops placed on a non-conducting plate and (ii) liquid metal discs placed between two horizontal non-conducting plates. As a test liquid we use Galinstan which is liquid at room temperate. The surface contours are observed using a high-speed camera system. The data are analyzed by utilizing both image and signal processing methods. In the experiments we control both electromagnetic parameters, i.e. the inductor current I and the current frequency f, as well as geometric parameters, i.e. drop volume V and disc height H, respectively). In the model configuration (i), upon increasing the inductor current we first observe a static drop squeezing. However, when the inductor current exceeds a certain critical value, these symmetric states become unstable to azimuthal waves. The amplitude, mode number, and oscillation frequency of the observed waves depend strongly on the control parameters. In the model configuration (ii) we observe only static large-amplitude deformations. Upon increasing the current, the ini-

tially circular disc undergoes a series of instabilities as it is deformed in a keyhole-type shape (mode 1), a boomerang-type shape (mode 2), a cloverleaf-type shape (mode 3), and a x-type shape (mode 4). These regular shapes are followed by several irregular shapes of even higher mode number including disc rupture.

Quasi-2D perturbations in duct flows under transverse magnetic field. **Alban Pothérat** (TU Ilmenau, Germany) GA/CT3068/014

Inspired by the experiment from iMoresco and Alboussiere (2004), we study the stability of a flow of liquid metal in a rectangular, electrically insulating duct with a steady homogeneous magnetic field perpendicular to two of the walls. In this configuration, the Lorentz force tends to eliminate the velocity variations in the direction of the magnetic field. This leads to a quasi-two dimensional base flow with Hartmann boundary layers near the walls perpendicular to the magnetic field, and so-called Shercliff layers in the vicinity of the walls parallel to the field. Also, the Lorentz force strongly opposes the growth of perturbations with a dependence along the magnetic field direction. On these grounds, we represent the flow using the model from Sommeria and Moreau (1982), which essentially consists of two-dimensional motion equations with a linear friction term accounting for the effect of the Hartmann layer.

The simplicity of this quasi-2D model makes it possible to study the stability and transient growth of quasi-two dimensional perturbations over an extensive range of non-dimensional parameters and reach the limit of High magnetic fields. In this asymptotic case, the Reynolds number based on the Shercliff layer $\mathrm{Re}/H^{1/2}$ becomes the only relevant parameter. Tollmien–Schlichting waves are the most linearly unstable mode as for the Poiseuille flow, but for $H \gtrsim 42$, a second unstable mode, symmetric about the duct axis, appears with a lower growth rate. We find that these layers are linearly unstable for $\mathrm{Re}/H^{1/2} \gtrsim \mathrm{Re}_c/H^{1/2} = 48350$ and energetically stable for $\mathrm{Re}/H^{1/2} \lesssim 65.32$. Between these two bounds, some non-modal quasi-two dimensional perturbations undergo some significant transient growth (between 2 and 7 times more than in the case of a purely 2D Poiseuille flow, and for much more subcritical valuesof Re). In the limit of a high magnetic field, the maximum gain $G_{\max}$ associated to this transient growth is found to vary as $G_{\max} \sim (\mathrm{Re}/\mathrm{Re}_c)^{2/3}$ and occur at time $t_{G\max} \sim (\mathrm{Re}/\mathrm{Re}_c)^{1/3}$ for streamwise wavenumbers of the same order of magnitude as the critical wavenumber for the linear stability.

Laminar–turbulent transition control of unsteady boundary layer on porous surface in a high fluid-flow acceleration. **Decan Ivanovic** (University of Montenegro, Montenegro and Serbia) GA/CT3296/010

The behavior of a boundary layer in the presence of a positive or negative pressure gradient along the surface is particularly important for the calculation of the surfaces drag as well as for the understanding of the processes which take in a diffuser section, because there is transition from laminar to turbulent flow which determines the dividing line between a region with low drag and one where drag is dramatically increased. So one can control laminar-turbulent transition and shear stress distribution by fluid which has been ejected or injected through the porose surface and this separation reduce is very important goal of flow manipulation. Apart from shear stress we are interested in knowing whether the boundary layer will separate under given circumstances and if so, we shall wish to determine the point of separation. The existence of a negative and in particular of a positive pressure gradient exerts a strong influence on the formation of laminar or turbulent layers. Generalized similarity method is used for calculation of this phenomena. Similar solutions of the boundary layer equations play an important role in the investigation of the stability of hydrodynamic flows and in developing semi-empirical crireria for the transition to turbulence. Through the porose surface in perpedicular direction the fluid of the same properties as incompressible fluid in basic flow, has been injected or ejected with velocity as a function of the contour longitudinal coordinate and time.The corresponding equations of unsteady boundary layer, by introducing the appropriate variable transformations, momentum and energy equations and two similarity parameters sets, being transformed into so-called universal, i.e. generalized for. These parameters are expressing the influence of the outer flow velocity, the injection or ejection velocity, and the flow history in boundary layer, on the boundary characteristics. Solutions, obtained by Tridiagonal Algorithm Method, are used to calculate the characteristic properties: velocity and vorticity distributions, shear stress, momentum and displacement thickness of unsteady boundary layer on porous aerofoil, especially near by separation point. It's found that for both in confuser and in diffuser aerofil regions the accelerating flow increases the shear stress and postpones the boundary layer separation, i.e. laminar-turbulent transition section.When the unsteady parameter is increasing the shear stess magnitude is increasing on whole aerofoil contour and the separation is removing along the surface. It means that the positive local acceleration leads to the postponing of the boundary layer separation in the diffuser region from 70

ICIAM 07 Congress Talks

00 Invited Speakers

01 Computing
(including: computational science and engineering, scientific computing, parallel computing, high performance computing, information technology, software engineering, the Web)

- 010: General
- 011: Knowledge and information systems
- 012: Numerics, algorithms
- 013: Data analysis and visualisation
- 014: Collaboration tools
- 015: None of the above, but in this section

02 Numerical Analysis
(including: numerical linear algebra, numerical methods for ODEs, DAEs, and PDEs, mesh generation)

- 020: Numerical linear algebra
- 021: Numerical methods for interpolation and approximation
- 022: Numerical methods for quadrature
- 023: Numerical methods for integral equations
- 024: Numerical methods for ODEs and DAEs
- 025: Numerical methods for PDEs: evolution problems
- 026: Numerical methods for PDEs: stationary problems

ICIAM Invited Lectures

IC/IT4980: *Dissipation inequalities in systems theory: past, present and future*
Frank Allgöwer (Universität Stuttgart, Germany)

Dissipation inequalities play a fundamental role in systems and control theory and dissipativity is a very useful concept in the analysis and design of nonlinear control systems. They were introduced in the early 1970s as a generalization of Lyapunov inequalities to systems having inputs and outputs. While Lyapunov functions serve to show the stability of dynamical systems, dissipation inequalities can be applied more widely, depending on the choice of the so-called supply rate. Classical cases being for example the well-known passivity or the L_2-norm characterization of nonlinear systems. Like in Lyapunov theory the biggest problem in applications is the construction of the storage function, which is the generalization of the Lyapunov function. However, for certain system classes, storage functions can be constructed systematically using for example backstepping techniques or recently developed tools from the area of computational semi-algebraic geometry, namely semi-definite programming and the sum of squares decomposition.

In this talk we will give a brief historical perspective and an introduction to the system theoretic concept of dissipation inequalities. We will present some recent results on dissipation inequalities; e.g., minimum phase analysis, stability analysis of nonlinear differential algebraic equation (DAE) systems, and nonlinear feedback and observer design that are based on novel dissipation inequalities and we will discuss questions concerning the computation of the storage functions. The methods will be demonstrated and critically assessed with various examples from engineering and systems biology.

IC/IT4959: *Compressive sampling*
Emmanuel Candès (California Institute of Technology, USA)

One of the central tenets of signal processing and data acquisition is the Shannon–Nyquist sampling theory: the number of samples needed to capture a signal is dictated by its bandwidth. Here we introduce a novel sampling or sensing theory which goes against this conventional wisdom. This theory, now known as *Compressed Sensing* or *Compressive Sampling*, allows the faithful recovery of signals and images from what appear to be highly incomplete sets of data; i.e., from far fewer measurements or data bits than used by traditional methods. We will present the key ideas underlying this new sampling or sensing theory, and will survey some of the most important results. We will emphasize the practicality and the broad applicability of this technique, and discuss what we believe are far reaching implications; e.g., procedures for sensing and compressing data simultaneously and much faster. Finally, there are already many ongoing efforts to build a new generation of sensing devices based on compressed sensing and we will discuss remarkable recent progress in this area.

IC/IT4881: *High-order methods for PDE's: recent advances and new perspectives*
Claudio Canuto (Politecnico di Torino, Italy)

Various paths (such as the hp-version of FEM or the spectral methods) have led over the years to the development of high-order discretization methods for boundary-value problems, which by now can be viewed under a unifying perspective.

We will discuss different issues related to the use of high-order methods. They include the design of efficient elemental bases, particularly in non-tensorial elements; the influence of the local parameters of meshsize and approximation order upon coercivity and $\inf$–$\sup$ constants, as well as *a-priori* and *a-posteriori* error bounds; the adoption of flexible domain partition strategies and the performance of the related algebraic solvers.

We will consider several applications, among which is the discretization of stochastic partial differential equations by means of high-order methods in the stochastic variables.

IC/IT4785: *Greedy algorithms: theory, applications and open problems*
Albert Cohen (Université Paris VI, France)

This talk will discuss computational algorithms that deal with the following general task: given a function f and a dictionary D of functions in a Hilbert space, extract a linear combination of N functions in D which best approximates the function f. In order to avoid combinatorial complexity, these algorithms use a greedy search for selecting the appropriate elements in the dictionary. We shall analyze their convergence properties as N tends to infinity, and discuss applications in various fields such as data compression, statistical learning theory and compressed sensing.

IC/IT4714: *Some fundamental issues in multi-scale modeling*
Weinan E (Princeton University, USA)

I will discuss two representative problems in multiscale modeling: the first is PDEs with multi-scale data; the second is multi-physics modeling. The first problem will be illustrated using standard elliptic equations with multi-scale coefficients. When the participating scales are separated, homogenization theory provides a very effective tool for reducing the complexity of such problems. We will address the question: What can we do when there is no scale separation or any other obvious structure that one can take advantage of in the coefficients? We will discuss a general principle for addressing questions of this

type, and the relevant mathematical and algorithmic issues.

The second problem will be illustrated using continuum and quantum mechanical models of solids such as tight binding models or density functional theory. Questions that will be addressed include: How do we obtain continuum models from quantum mechanical models? How do we formulate coupled quantum/continuum models? How do we design efficient algorithms? The answer to these questions relies on a mathematical understanding of the quantum mechanical models.

IC/IT4501: *Introduction to persistent homology*
Herbert Edelsbrunner (Duke University, USA)

Persistent homology is an algebraic tool for measuring topological features of shapes and functions. It casts the multi-scale organization we observe in nature into a mathematical formalism. This talk will introduce the basic concepts, present a few applications, and survey extensions of the original concept motivated by applications.

IC/IT4967: *New developments in dynamic pricing and hedging and measuring financial risk*
Nicole El Karoui (École Polytechnique, Palaiseau, France)

A large number of strategies are proposed on financial markets to control risks induced by market trend and market fluctuations. Traditional or more sophisticated (exotic) financial products are used by businesses or investors to transfer their risks to financial institutions.

Important questions faced by the market risk industry; e.g., the development of asset pricing models and hedging strategies based on daily (infinitesimal) risk management criteria, have found answers through probabilistic tools and concepts, such as Brownian motion, martingales, and stochastic control and related fields. This in turn has had an important impact on the (exponential) development of this industry.

Numerical implementation is the cornerstone of the modelling process. The choice of a model is hence driven not only by its theoretical properties but also, and in great part, by its numerical tractability. This includes, among other things, reliable estimation of parameters, which are inferred from observable market data (financial products prices). Over the last few years, techniques for stabilizing these ill-posed problems via fast and accurate algorithms in partial differential equations have been developed. In other respects, with motivation coming from multidimensional problems, Monte Carlo methods have been revisited in order to obtain accurate numerical results for prices of high-dimensional products or their derivatives with respect to key parameters. Efficient methods are based on differentiation on Wiener space and Malliavin calculus. A recent topic is that of solving optimization problems (optimal stopping times, optimal portfolio) through Monte Carlo methods.

Thanks in part to the size reached by derivatives markets, market authorities now require financial institutions to compute their daily global exposure (Value at Risk) via their own *internal* models. Motivated by this challenge, academic and risk-managers are debating the *best concept* of risk measure and various problems induced by the high-dimensional character of the covariance matrices they deal with. Mathematical finance is a challenging and fast evolving domain, constantly looking for new ideas and concepts in Mathematics. One of its very remarkable aspects is the ability of theoretical research to have direct implications on daily market practice.

IC/IT4440: *Order-value optimization and new applications*
José Mario Martínez (Universidade Estadual de Campinas, Brazil)

Order-value optimization (OVO) is a family of problems in which the objective function depends of the relative position of a set of real components for each point in the domain. These problems are generally difficult because convexity and smoothness of the components are not inherited by OVO objective functions. Primal methods that converge to suitable defined stationary points have been developed. Reformulations of OVO as smooth (and large) nonlinear programming problems are also available. Applications include robust parameter estimation, risk minimization, protein alignment, structural alignments, computer vision, separate-variable optimization, and many others.

IC/IT4965: *Pattern formation in micromagnetics*
Felix Otto (Universität Bonn, Germany)

Micromagnetics deals with the spatial pattern formed by the magnetization of a ferromagnet. From the point of view of mathematics, micromagnetics is an ideal testbed for a pattern-forming system in materials science: There are abundant experiments on a wealth of visually attractive phenomena and there is a well-accepted continuum model.

In this talk, I will focus on a couple of specific experimental pattern for thin film ferromagnetic elements. Starting point for our investigation is the micromagnetic model which has several characteristic length scales and thus many parameter regimes. For the pattern under consideration, we identify the appropriate paramater regime and rigorously derive a reduced model. We analytically investigate and numerically simulate the reduced model and compare its predictions to experimental data from our collaborators.

IC/IT4788: *Computing, business and applied mathematics: the next challenges*
William Pulleyblank (International Business Machines (IBM), USA)

There have been two consistent drivers over the last sixty years of the evolution of computing: Computer power and price/performance improve by a factor of two every eighteen months; the problems that we wish to solve require this growth in capability and more.

We seem to be reaching inflection points with both of these drivers. High performance systems are resorting to massive parallelism to continue the required growth in performance. The new challenges arising in business and industry are requiring the solution of fundamentally different problems as well as the development of new approaches to old problems.

I will discuss both of these issues and some approaches that are being applied, with varying degrees of success. In particular, I will focus on some of the challenges that arise in telecommunications, particularly related to the business models. I will also discuss what I believe are some of the significant challenges that we will face in the future.

IC/IT4485: *Sampling function space: applications and algorithms*
Andrew Stuart (University of Warwick, UK)

Many problems arising in applications require the sampling of a measure on function space. A particular structure that often arises is when the measure has Radon–Nikodym derivative with respect to a Gaussian measure. We introduce MCMC methods for sampling such measures, and study their complexity as a function of the dimension n of the approximating space. The measures in question may be viewed as having a multiscale structure in which a spectrum of scales is present. This spectrum is manifest in the Kahunen–Loeve representation of the reference Gaussian measure.

We start the talk with various illustrations from the fields of econometrics, transition path sampling, signal processing and data assimilation. We then illustrate the unifying mathematical structure underlying all these problems. This leads naturally into the study of algorithms for such problems, and their computational complexity.

IC/IT4734: *Network formation games*
Éva Tardos (Cornell University, USA)

Large computer networks such as the Internet are built, operated and used by a large number of diverse and competitive entities. In light of these competing forces, it is surprising how efficient these networks are. It is an exciting challenge to understand the success of these networks in game theoretic terms: what principles of interaction lead selfish participants to form such efficient networks? In this talk we present a number of network formation games. We focus on simple games that have been analyzed in terms of the efficiency loss that results from selfishness.

IC/IT4962: *Minimum-volume ellipsoids: applications, duality and algorithms*
Michael Todd (Cornell University, USA)

We consider the problem of finding a minimum volume ellipsoid containing a finite set of points in $\mathbb{R}^d$. This problem has applications in data analysis (clustering, detection of outliers or a small core set), robotics (detecting collisions), and statistics (its dual is the optimal design problem). It has a rich duality theory, which suggests effective algorithms. For large-scale problems, first-order methods exploiting the structure of the problem are most efficient; while these were discovered in the '70s, they were rediscovered recently and their computational complexity and asymptotic convergence analyzed.

IC/IT4947: *How to make invisible objects visible and visible objects invisible*
Gunther Uhlmann (University of Washington, USA)

We will describe the method of complex geometrical optics and its applications to find acoustic, quantum, and electromagnetic parameters of a body by making measurements at the boundary of the body. We will also survey recent results on how to make objects invisible to electromagnetic waves.

IC/IT4506: *Nonlinear problems involving integral operators*
Luis Caffarelli (University of Texas at Austin, USA)

We will present several problems and approaches to treat nonlinear problems involving integral diffusions, more precisely, fractional powers of the Laplacean: regularity and stability of solutions and free boundaries for free-boundary problems coming from boundary control, semi-permeable membranes, and constrained Levi processes.

IC/IT4751: *Parabolic PDEs and deterministic games*
Robert Kohn (Courant Institute, NYU, USA)

We usually think of parabolic partial differential equations and first-order Hamilton–Jacobi equations as being quite different. Parabolic equations are linked to random walks, and often arise as steepest-descents; Hamilton–Jacobi equations have characteristics, and often arise from optimal control problems.

In truth, these equations are not so different. I will discuss recent work with Sylvia Serfaty, which provides deterministic optimal-control interpretations of many parabolic PDE. In some cases, for example motion by curvature, the optimal control viewpoint is very natural, geometric, and easy to understand. In other cases, for example the linear heat equation, it seems a bit less natural, and therefore even more surprising.

IC/IT4755: *Recent trends in robust convex optimization*

Arkadi Nemirovski (Georgia Institute of Technology, USA)

The data in real-life optimization problems usually are uncertain; that is, not known exactly when the problem is to be solved. Examples demonstrate that even small perturbations of uncertain data can make the optimal solution corresponding to the *nominal* data values heavily infeasible; and thus, practically meaningless. Robust Optimization methodology proposed in mid-90s and rapidly developing since then is aimed at building *robust optimal* solutions (those remaining feasible for all realizations of the data from a given uncertainty set), and optimizing under this restriction a given objective function.

In the talk, we outline the basic concepts of RO in the context of uncertain *well-structured* convex optimization problems (linear, conic quadratic and semi-definite programming), with emphasis on recent extensions of the RO paradigm and on the central issue of computational tractability/building tight tractable approximations of the robust counterparts of uncertain problems. We intend also to discuss recent links between RO and Chance Constrained Stochastic Programming, a more traditional way to handle data uncertainty in Optimization.

IC/IT4558: *Chaotic itinerancy reality in brain dynamics*

Ichiro Tsuda (Hokkaido University, Japan)

Motivated by the recent finding of transitory dynamics on the brain activity, we have studied high-dimensional chaotic dynamical systems related to neural systems. In the first part of the talk, we would like to focus on chaotic itinerancy as a key concept for understanding the observed transitory phenomena. In the second part, we provide a mathematical model for the hippocampus in order to clarify the mechanism of the formation of episodic memory. The model produces transitory dynamics which is similar to what observed in the hippocampus. The detailed numerical studies clarified that the transitory dynamics can be represented by chaotic itinerancy. Furthermore, the model predicts that the time series in the transitory dynamics can be encoded by Cantor sets in the state space of neurons. We show that this prediction has been proven in the experiments on the hippocampus.

IC/IT4851: *Design, analysis and application of optimal PDE solvers*

Jinchao Xu (Pennsylvania State University, USA)

This talk is devoted to optimized numerical methods for partial differential equations (PDEs) by an integrated design and application of discretization, grid adaptation and algebraic solution of the resulting discrete systems. After giving a general perspective, a number of recent results will be presented to demonstrate that many linear and nonlinear PDEs (such as model equations for electromagnetic, complex fluids and fuel cells) can be practically solved with (nearly) optimal computational complexity.

Johnson–Segalman and other mathematical models for non-Newtonian fluids are among the examples to be discussed. A sophisticated finite element scheme (recently developed jointly with Y. Lee) will be reported for these nonlinear systems. This scheme is stable for any size of the Weissenberg number (while almost all other existing discretizations suffer from the well-known High Weissenberg Number Problem), and, at each time step, its discretized system is reduced to one linear system and a number of independent ODEs that can be solved in parallel.

Algebraic systems resulting from such properly discretized PDEs can be effectively solved by multilevel methods based on subspace correction and auxiliary space precondition. By using new convergence criteria and estimates (from joint works with L. Zikatanov, J. Wu and Y. Lee) for these methods, robust algorithms are developed for a large class of singular, nearly singular and indefinite system of equations. The method of subspace correction is shown to be uniformly convergent for nearly singular system if the underlying near-null space can be linearly represented by its intersection with all relevant subspaces. The method of auxiliary space preconditioning is applied (in a recent joint work with R. Hiptmair) to construct optimal preconditioners for $H(\mathrm{curl})$ and $H(\mathrm{div})$ systems based on user-friendly solvers (such as algebraic multigrid methods) for Poisson-like equations.

IC/IT4523: *Topology optimization of structures*

Grégoire Allaire (École Polytechnique Palaiseau, France)

The typical problem of structural optimization is to find the *best* structure which is, at the same time, of minimal weight and of maximum strength or which performs a desired deformation. In this context I will present the combination of the classical shape derivative and of the level-set method for front propagation. This method has been implemented in two and three space dimensions for models of linear or non-linear elasticity and for various objective functions and constraints on the perimeter. It has also been coupled with the bubble or topological gradient method which is designed for introducing new holes in the optimization process. Since the level set method is known to easily handle boundary propagation with topological changes, the resulting numerical algorithm is very efficient for topology optimization. It can escape from local minima in

a given topological class of shapes and the resulting optimal design is largely independent of the initial guess. I will discuss various applications and numerical examples.

IC/IT4958: *Contact problems in solid mechanics*
Michel Fortin (Université Laval, Canada)

Contact problems are industrially important and present a number of difficult mathematical issues: they are free-boundary problems, which are described by a quasi-variational inequality. We shall address some issues related to these problems.

- Discretisation implies a mixed finite element analysis. Stability is obtained in weak spaces, which implies trouble in numerical computation. We shall present some choices of elements, which are suitable for three-dimensional computation.
- Well-posedness of the classical Coulomb's law is not clear: the frictional threshold depends on a variable for which point values are far from being defined.

We shall also present an algorithm for the numerical solution, based on a conjugate gradient method with projection. It will be employed to solve a sequence of Tresca's problems with an external iteration on the threshold. As we shall discuss, use on the Coulomb's cone induces a loss of symmetry, which impairs the convergence of gradient methods.

Real problems also imply geometrical difficulties, especially when two deformable bodies get in contact. Some of these problems will be treated correctly but other ones only through heuristic considerations. Finally, mesh adaptation appears to be an important technique to provide accurate and usable computations. Numerical results will also be presented.

IC/IT4368: *Numerical methods for nonlinear elliptic problems*
Roland Glowinski (University of Houston, USA)

The main goal of this lecture is to address the *numerical solution* of several classes of *nonlinear elliptic problems*. This includes *nonlinear eigenvalue problems* such as

$$-\Delta u = \lambda u^3 \tag{1}$$

and *fully nonlinear elliptic equations* of the Monge–Ampère type. It will be shown, that by well chosen combinations of finite element approximations, least-squares formulations and operator-splitting methods one can build a methodology which is robust and flexible, and which provides for some of the problems under consideration (the elliptic Monge–Ampère equation for example) an alternative to the methods based on the concept of viscosity solutions. Actually, it will be shown, via an appropriate transformation, that some of the least-squares methods to be discussed are viscosity solutions but in a sense different from Crandall and P.L. Lions. The results of various numerical experiments will be presented. They concern, in particular, the solution of Monge–Ampère type equations and the computational investigation of some examples of the above equation.

IC/IT4970: *Asymptotic solutions of Hamilton–Jacobi equations for large time and related topics*
Hitoshi Ishii (Waseda University, Japan)

I will discuss recent developments on the study of the asymptotic behavior, as $t \to \infty$, of solutions $u = u(x,t)$ of Hamilton–Jacobi (HJ for short) equations $\partial u/\partial t + H(x, Du(x,t)) = 0$ in $\mathbb{R}^n \times (0,\infty)$, where $H : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}$ is a continuous function and $Du = (\partial u/\partial x_1, ..., \partial u/\partial x_n)$. Hamilton–Jacobi equations are basic equations in the dynamic programming approach to optimal control and differential games. S. N. Kruzkov in the 60s and P.-L. Lions and G. Barles in the 80s initiated the study of the large-time behavior of solutions of HJ equations.

In the last decade many authors, including G. Namah, J.-M. Roquejoffre, A. Fathi, G. Barles, P. E. Souganidis, A. Davini, A. Siconolfi, Y. Fujita, P. Loreti, ..., investigated the aymptotic behavior of large-time solutions of HJ equations under the influences of or interaction with weak KAM theory as it was developed by A. Fathi and A. Siconolfi among others. My talk will cover:

(i) the additive eigenvalue problem (ergodic control problem) for HJ equations;
(ii) the weak KAM theory and representation theorems for solutions of HJ equations;
(iii) the asymptotic behavior of solutions of HJ equations.

IC/IT4516: *Hyperbolic conservation laws: past and future*
Barbara Keyfitz (Fields Institute, Canada)

The field of conservation laws (quasilinear hyperbolic partial differential equations) has captured the attention of mathematics researchers, computational fluid dynamicists, and modelers of physical and engineering phenomena for over 70 years. This talk will survey some of the power, and some of the limitations, of the conservation law approach to modeling. It will also expound some of the major achievements in establishing a mathematical theory, and discuss why theoretical advances have been so slow, and why so much still seems to remain out of reach. Finally, I will describe recent work of a number of people on establishing mathematical properties of shock reflection phenomena.

IC/IT4552: *Mathematics sets the molecular world in motion*
Christof Schütte (Freie Universität Berlin, Germany)

Since several decades Molecular Dynamics (MD) has been a field of world-wide research activities. Until recently it has mainly been focussed towards the prediction of the minimal-energy geometry of a molecule and the computation of statistical quantities like transport coefficients or free energies. Progress in molecular biophysics and molecular chemistry, as well as in materials science, has made it clear that the effective dynamical behavior of a molecular system is essential for its functions/properties. However, available experimental techniques do not suffice to understand the effective dynamics in appropriate detail. In addition, direct MD simulation of the effective dynamics of many molecular systems is infeasible even on the fastest computers of today and the foreseeable future, since the typical timescale of interest is many (typically more than 10) orders of magnitude larger than the fastest scales that have to be resolved.

Recent progress in mathematical modelling, in combination with novel simulation strategies and new experimental techniques, has brought us much closer to solving this problem. The talk will introduce the mathematical background of the problem, explain what is meant by effective dynamics, define the mathematical objects that are required to appropriately understand it (almost invariant/metastable sets, transition rates, transition paths), present algorithmic concepts for their efficient computation, and illustrate the resulting insight into the effective dynamics of some molecular systems of biological interest.

IC/IT4122: *Controllability and observability: from ODEs to quasi-linear hyperbolic systems*

Tatsien Li (Fudan University, PR China)

By means of the semi-global classical solution, a simple and direct constructive method is presented to give a complete result with applications on the exact boundary controllability and the exact boundary observability for 1-D quasilinear hyperbolic systems with general nonlinear boundary conditions.

IC/IT5010: *Radar imaging*

Margaret Cheney (Rensselaer Polytechnic Institute, USA)

Synthetic-aperture radar imaging is a technology that has been developed, very successfully, within the engineering community during the last 50 years. Radar systems now make beautiful and very useful images of our earth and other planets. One of the key components of this impressive technology is mathematics, and many of the open problems are mathematical ones.

This lecture will explain, from first principles, the basics of radar and some of the mathematics involved in producing high-resolution radar images. The talk will conclude with a quick survey of some of the specific problems on which more mathematical work is needed

01: Computing

Computing, Minisymposia

IC/MP55/015: Applied analysis meets scientific computing.

Organiser: Laurent Demanet (California Institute of Technology, USA)
Co-organiser: Lexing Ying (University of Texas at Austin, USA)

This minisymposium will focus on some recent ideas for efficient computation of the wave and Helmholtz equations. These ideas have in common that they aim at high, controlled accuracy using a minimum number of degrees of freedom through adequate representations. 1) A first research avenue is the multipole expansion for convolution with the Helmholtz kernel, which allows to solve the second-kind boundary integral equations for surface scattering with remarkable speed and accuracy. 2) A second research avenue are the geometric multiscale expansions of wave propagators inspired by the second dyadic decomposition. These methods include curvelets, wave atoms, and symbol separation. For the wave equation, they offset the need for traditional timestepping through manipulations of operators in compressed form. For related oscillatory integrals, they offer near-optimal complexity algorithms. 3) A third research avenue is computation of eigenfunctions of the Laplacian in bounded domains through superposition of Helmholtz kernels and generalized Green's identities. This alternative approach currently yields the most accurate codes for quantum billiards and waves inside complicated cavities. We hope this minisymposium will help highlight the similarities and complementarity of these three approaches.

Operator-based wave computations. **Laurent Demanet** (California Institute of Technology, USA) IC/MT2556/010

This talk presents a new algorithm for linear hyperbolic PDE with smooth coefficients, based on a formulation of the Green's function that uses Fourier integral operators. The computation mostly involves manipulations of operators in compressed form, which can be done in complexity essentially independent of the resolution of the initial data. This stratgey becomes advantageous in regimes where the wavefields are very oscillatory. Operators are compressed and manipulated using techniques such as phase-space partitionings, traveltime computations via the phase-flow method, low rank matrix approximations via random sampling, special quadratures that exploit the geometry of the canonical relation, etc. This is joint work with Lexing Ying.

Combining finite differences/finite elements with geometrical wave propagation in 1D. **Christiaan Stolk** (Universiteit Twente, The Netherlands) IC/MT3000/010

We show that the initial value problem for a strictly-hyperbolic partial differential equation on the circle can be solved at cost $O(N)$. To obtain this, the equation is approximately decoupled, into first order equations that can be solved using the method of characteristics. The error satisfies an ODE in a function space, that is of the form $du/dt = R(t)u$, with $R(t)$ a bounded operator. With an appropriately designed scheme, using time-steps longer than allowed by the CFL condition in FD/FE schemes, this leads to the stated complexity. The main assumption is that the coefficients in the PDE vary on a longer scale than the initial values. An implementation of the new method performs comparable or better than standard fourth order finite differences in examples of this kind.

Global approximation methods for high-frequency eigenmodes. **Alex Barnett** (Dartmouth College, USA), Timo Betcke (University of Manchester, UK) IC/MT3489/010

The efficient computation of eigenmodes has applications to both engineering problems (acoustics, optical cavities) and more fundamental problems of mathematical physics (quantum chaos, spectral geometry, automorphic forms). The interesting case of high-frequency (system is many wavelengths across) remains numerically challenging. The use of global basis approximation by Helmholtz solutions, combined with matching on the boundary, has undergone a revival due to a recent convergence of ideas from the physics and numerical analysis communities. I will present various global basis sets, discuss the mode of failure of plane-wave bases, and demonstrate the success of fundamental solutions (with origins placed outside the domain) in a large class of 2D domains. The latter basis achieves high accuracy with as few as 3 degrees of freedom per wavelength on the boundary. I present some open questions regarding the convergence rate of such bases. Finally I present a further advantage of such methods: that acceleration (scaling) methods exist which allow a further increase in speed by $O(k)$, where k is the wavenumber. Some of this talk covers joint work with T. Betcke.

A fast phase-space method for computing creeping waves. **Olof Runborg** (Kungliga Tekniska högskolan, Sweden) IC/MT4979/010

Creeping rays can give an important contribution to the solution of medium to high frequency scattering problems. They are generated at the shadowlines of the illuminated scatterer and propagate along geodesics on the scatterer surface, continuously shedding diffracted rays in their tangential direction. We show how the ray propagation problem can be formulated as a partial differential equation (PDE) in a three-dimensional phase space. The PDE solution give information about all possible creeping rays. Computationally the cost of solving the PDE is less than tracing all rays individually. We show numerical results and an application to monostatic radar cross section problems where creeping rays from all illumination angles must be computed.

IC/MP162/015: Microlocal analysis meets scientific computing.

Organiser: Laurent Demanet (California Institute of Technology, USA)
Co-organiser: Lexing Ying (University of Texas at Austin, USA)

Various theories and algorithms have recently been developed to better exploit the microlocal nature of wave-based or tomographic inverse problems. Microlocal analysis is the mathematical study of singularities of functions in phase-space, and how those singularities are transformed by linear operators and PDE. For example, the problem of recovery of the index of refraction of a medium from high-frequency wave measurements is generally convexified and much simplified when only the singularities are studied. The objects to compute in this setting are often generalized Radon transforms or Fourier integral operators. In contrast to traditional PDE or integral equation solvers, microlocal numerical methods consider the map-

ping of singularities as the entity of interest (the canonical relation itself) and discretize it either 1. through direct sampling, or 2. through phase-space tilings, or 3. through diffeomorphisms. The emphasis of this minisymposium will be on inverse problems and on the above-mentioned three algorithms for solving them; with applications to imaging of singularities in reflection seismology, and rendering of hard shadows due to occluders in computer graphics.

Microlocal computation of hard shadows. **Gabriel Peyré** (Université de Paris–Dauphine, France) IC/MT2870/010

Accurately rendering hard shadows (sharp luminosity constrasts) is one of the main challenges of computing illumination of 3D scenes in animated movies. The difficulty is due to the high-dimensionality and the singularity of the integral kernel of the so-called radiance equation governing shadow forming. Contemporary rendering methods are based on Fourier or Monte Carlo methods that are completely oblivious to the geometry of this integral kernel. In joint work with Laurent Demanet, we propose a different viewpoint: the map linking the light source to the shadow boundary is very well expressed, in the language of microlocal analysis, as a relation between wavefronts in phase-space. We call it the "light-shadow relation". Its explicit computation is an integral part of an envisioned algorithm for computing hard shadows much more efficiently than previously. This microlocal viewpoint also ties in with sparse wave packet (curvelet, bandelet) techniques for representing the radiance integral operator. We hope to report on preliminary numerical results.

Travel-time tomography. **Gunther Uhlmann** (University of Washington, USA) IC/MT3259/010

We consider the inverse problem of determining the anisotropic index of refraction of a medium by measuring the travel times of waves going through the medium. In mathematical terms this consists in determining the Riemannian metric of a Riemannian manifold with boundary from its lengths of geodesics (i.e multiple arrival times.)

We will also consider a very related problem in phase space. Assume that we know for every geodesic going through the medium its point of entrance and direction of entrance and its point of exit and direction of exit. This information is encoded in the scattering relation. Can we recover the Riemannian metric (i.e. index of refraction) from the scattering relation?

A multi-scale approach to evolution equations with applications in wave-equation imaging. **Maarten de Hoop** (Purdue University, USA) IC/MT3262/010

Downward continuation based imaging and wave-equation reflection tomography can essentially be expressed in terms of solving particular evolution equations. The underlying model describes the single scattering of waves in a background medium. Here, we are concerned with developing a method that admits background media of limited smoothness, which leads to evolution equations generated by certain pseudodifferential operators. We develop a multi-scale approach to solving such evolution equations, while making use of solution representations based on wavepackets or a (co)frame of curvelets and a (curvelet-curvelet) scattering series. We discuss results concerning the 'concentration' of curvelets. We also discuss computational aspects of the method that leads us to an approach that departs from the use of (co)frames.

Joint research with H. Smith (UW), G. Uhlmann (UW), F. Andersson (Lund).

Fast directional multilevel computation for problems with oscillatory kernels. **Lexing Ying** (University of Texas at Austin, USA) IC/MT4799/010

We introduce a new directional multilevel algorithm for solving the N-body or N-point problems with highly oscillatory kernels. These problems often result from the boundary integral formulations of scattering problems and are difficult due to the oscillatory nature of the kernel and the non-uniformity of the particle distribution.

We address the problem by first proving that the interaction between a ball of radius r and a well-separated region has an approximate low rank representation, as long as the well-separated region belongs to a cone with a spanning angle of $O(1/r)$ and is at least $O(r^2)$ away from from the ball. We then propose an efficient and accurate procedure which utilizes random sampling to generate such a separated, low rank representation. Based on the resulting representations, our new algorithm organizes the high frequency far field computation in a multidirectional and multiscale strategy to achieve maximum efficiency.

The algorithm performs well on a large group of highly oscillatory kernels. Assuming that the points are sampled from a two dimensional surface, our algorithm has provably $O(N \log N)$ complexity for any given accuracy. We also provide numerical results to demonstrate these properties.

IC/MP164/015: High-dimensional analysis meets scientific computing.

Organiser: Laurent Demanet (California Institute of Technology, USA)
Co-organiser: Lexing Ying (University of Texas at Austin, USA)

This minisymposium will focus on scientific computing in high dimensions. The attainable size of simulations using textbook methods, when used in $\mathbb{R}^d$, with d large, typically scales at best like the $1/d$-th power of computer performance. While this phenomenon is already a problem for physics in $\mathbb{R}^3$, truly high-dimensional problems include the multiparticle Schrödinger equation, reflection seismology with its high-dimensional acquisition manifolds, and kinetic gas theories in phase-space. Fortunately, adapted techniques have emerged over the past few years to better redefine what computations need to be done and what data need to be stored for solving high-dimensional PDE.

(1) One of these methods is sparse grids, where boundedness of the mixed partial derivatives is used to cut down the complexity of sampling;

(2) another such method is H-matrices, where partitioned low-rank representations are available for kernels of large classes of integral equations;

(3) finally, separated representations generalize the notion of low rank and SVD to tensors of order higher than 2.

All these methods, and others, should be discussed in this minisymposium.

$\mathcal{H}^2$-matrices. **Steffen Börm** (Max-Planck-Institut Leipzig, Germany) IC/MT2709/010

Hierarchical matrices are data-sparse representations of dense matrices which make it possible to perform operations like matrix-vector multiplication, matrix addition, multiplication or inversion in almost linear complexity. Due to this property, hierarchical matrices can be used to construct preconditioners for integral or partial differential equations and to solve problems from control theory.

$\mathcal{H}^2$-matrices combine the basic ideas of hierarchical matrices with those of multilevel methods in order to perform certain operations in "true" linear complexity.

The basic idea is that matrix blocks corresponding to domains which are far do not contain a singularity can be represented in the factorized form $VSW^\top$, where the matrices V and W describe the basis in which the block is expressed and S contains the corresponding coefficients. The key problem of $\mathcal{H}^2$-matrix arithmetics is the construction of suitable bases. For integral equations, it can be solved by using polynomial interpolation or multipole expansion, possibly with subsequent algebraic optimization. The same optimization techniques can also be applied to general matrices.

In the case of integral operators, $\mathcal{H}^2$-matrices can be interpreted as efficient representations of the $(2d)$-dimensional kernel function. Although typical kernel functions do not satisfy the standard regularity assumptions of sparse grid or Kronecker tensor techniques, they can still be approximated by $\mathcal{H}^2$-matrices corresponding to block-tensor decomposition of the computational domain.

Adaptive wavelet algorithms for PDEs on product domains. **Rob Stevenson** (Universiteit Utrecht, The Netherlands), Christoph Schwab (ETH Zürich, Switzerland) IC/MT2745/010

With standard isotropic approximation by (piecewise) polynomials of fixed order in a domain $D \subset \mathbb{R}^d$, the convergence rate in terms of the number N of degrees of freedom is inversely proportional to the space dimension d. This so-called *curse of dimensionality* can be circumvented by applying sparse tensor product approximation, when certain higher order mixed derivatives of the approximated function happen to be bounded in L_2. Solutions of PDEs, however, satisfy this condition in special situations only.

Considering best N-term approximation from tensor product wavelet bases, in [*Constr. Approx.*, 24 (1) (2006), 49-70], Nitsche showed that the above regularity constraint can be dramatically reduced to a condition that is satisfied by the solutions of (elliptic) PDEs. Adaptive wavelet algorithms realize convergence rates as that of best N-term approximations in linear complexity *assuming* that the infinite stiffness matrix of the operator with respect to such a basis is highly compressible. Applying piecewise smooth wavelets, we verify this compressibility for general, non-separable elliptic PDEs in tensor domains, with that demonstrating optimality of the adaptive wavelet algorithms. We hope to be able to illustrate our theoretical considerations by numerical results.

Hierarchical low-Krönecker-rank approximation. **Lars Grasedyck** (Max-Planck-Institut Leipzig, Germany) IC/MT3338/010

The treatment of high-dimensional PDEs is in particular challenging because of the curse of dimension, i.e., that the dimension d enters the complexity exponentially for naive approaches. One method to avoid the curse is to use efficient compressions on full tensor grids. Even though the full space contains $\mathcal{O}(N^d)$ degrees of freedom, associated grid functions can be approximated with much less data. The idea is to approximate discrete vectors x in this space by low Kronecker rank $k \ll N^d$:

$$x_{i_1,\dots,i_d} \approx \sum_{\nu=1}^{k} \prod_{j=1}^{d} y_{\nu,i_j} =: y_{i_1,\dots,i_d}, \qquad i_j \in \{1,\dots,N\}.$$

The Kronecker rank k vector y is represented by kdN data, i.e. with a complexity that scales multi-linearly in the dimension d, the number of mesh points N per axis and the Kronecker rank k.

In this talk we will focus on the question how one can compute with vectors in the compressed low Kronecker rank representation. We consider on the one hand side a high-dimensional PDE where the right-hand side has low Kronecker rank. There, we can prove that the solution allows for a low Kronecker rank approximation and we can derive explicit formulae for the solution in this format. The format involves matrix exponentials which are treated by hierarchical matrix techniques in almost linear complexity.

On the other hand we present methods for the efficient truncation from a larger Kronecker rank K to a smaller Kronecker rank $k < K$. This truncation then allows the use of iterative solvers for systems where the inverse does not allow for an explicit formula.

Preliminary results on approximating a wavefunction as an unconstrained sum of Slater determinants. **Gregory Beylkin** (University of Colorado at Boulder, USA), Martin Mohlenkamp (Ohio University, USA), Fernando Pérez (University of Colorado at Boulder, USA) IC/MT5044/010

A multiparticle wavefunction, which is a solution of the multiparticle Schrödinger equation, satisfies antisymmetry condition, thus making it natural to approximate it as a sum of Slater determinants. Many current methods do so but, in addition, they impose structural constraints on the Slater determinants, such as orthogonality between orbitals or a particular excitation pattern. By removing these constraints, we hope to obtain much more efficient expansions.

We use an integral formulation of the problem, a Green's function iteration, and a fitting procedure based on the computational paradigm of separated representations. For constructing and solving a matrix-integral system of equations derived from antisymmetric inner products, we develop new algorithms with computational complexity competitive with current methods.

We describe preliminary numerical results and make some observations.

IC/MP283/010: Parallel Matlab.

Organiser: John Gilbert (University of California, Santa Barbara, USA)

As the computational demands of scientific modeling and simulation rise, and the cost of parallel computing hardware drops, more and more computational scientists wish to use parallel computation. Matlab is an extremely popular language and interactive environment for doing computational science on workstations. There is a clear motivation to make it possible to run Matlab programs on very large problems using parallel computers.

The speakers in this minisymposium will describe a number of projects that are building parallel implementations of the Matlab language. Cleve Moler, Chief Scientist of The MathWorks and the developer of Matlab, will describe his work on Parallel Matlab. Alan Edelman of MIT and Interactive Supercomputing Inc. will present Star-P, an interactive system that allows computational scientists to use the Matlab language to program parallel supercomputers and commodity clusters. Ashok

Krishnamurthy (Ohio State University and the Ohio Supercomputing Center) will discuss the application of several parallel implementations of Matlab in image processing. John Gilbert (UC Santa Barbara) will describe a set of tools for computing on large graphs that is based on the parallel sparse array implementations in Matlab and Star-P.

The star-P parallel platform for use with Matlab®, Python, and symbolic software. **Alan Edelman** (Massachusetts Institute of Technology, USA) IC/MT4196/010

The Star-P parallel platform allows Matlab users, and users of other languages, to program in parallel in an open easy to use environment. We will show the details underlying the system and what users need to know to write effetive parallel codes.

Parallel Matlab. **Cleve Moler** (The MathWorks, Inc., USA) IC/MT1621/010

In the MathWorks design of Parallel MATLAB, each node of a multiprocessor computing environment executes a program written in the MATLAB programming language. Key features of the system include parallel for loops, distributed arrays, and global reductions. We will describe these features in more detail and demonstrate them with several examples. Our motto is "Think Matrices, Not Messages".

Performance metrics and measurements for PGAS Matlab implementations. **Ashok Krishnamurthy** (Ohio Supercomputer Center, USA) IC/MT4212/010

Matlab is a widely popular scientific programming tool. As applications written in Matlab have required larger data sets and more computational power, parallel extensions for Matlab have emerged. One notable category of parallel Matlab extensions are those that provide partitioned global address space (PGAS) support. PGAS is a programming model in which an application is viewed as a collection of concurrent threads that can communicate with one another via a globally shared data space. PGAS provides a high-level abstraction for parallel programming and pairs quite naturally with the array-based notation of Matlab.

However, it is not enough to merely write parallel code; developers want to create efficient parallel code. In that regard, a tradeoff exists between the abstractions provided by the PGAS model and the specifics of the architecture impacting the execution. A number of recent efforts in PGAS performance metrics and measurements such as the global address space performance (GASP) tool show promise in providing performance feedback to developers.

In this paper, we consider performance measurements and metrics for two PGAS versions for Matlab: MathWorksŠ proprietary Distributed Computing Toolbox/Distributed Computing Engine (DCT/DCE) and an open source solution known as pMatlab+bcMPI. We describe a relevant set of PGAS metrics and describe the implementation of a set of common performance measurements. We ran a number of benchmarks relevant to the signal processing domain with each version on a cluster and present results correlating the metrics with the actual parallel efficiency. We feel that the data validate the utility of these metrics in tuning applications for improved parallel efficiency.

A high-performance interactive environment for exploring large graphs. **John Gilbert** (University of California, Santa Barbara, USA) IC/MT3239/010

High-performance computing is being used to understand large data sets that are combinatorial rather than numerical in nature, in applications as diverse as sparse matrices, knowledge discovery, machine learning, search and information retrieval, and computational biology.

Compared to numerical supercomputing, the field of high-performance combinatorial computing is in its infancy. How can combinatorial methods be used by people who are not experts in discrete mathematics? How can supercomputers be used by people who need to explore huge discrete data sets interactively?

We are using a parallel dialect of Matlab to build a flexible, scalable interactive environment for high-performance computation on discrete structures that will be used both as a rapid-prototyping tool for exploring and experimenting with different approaches to analysis, and as a scalable system for performing analysis on real, dynamic, discrete data.

IC/MP263/011: Math on the web: content development and implementation.

Organiser: Daniel Lozier (National Institute of Standards & Technology, USA)
Co-organiser: Abdou Youssef (The George Washington University, USA)
Co-organiser: Bruce Miller (NIST, USA)

Since the advent of the Web, various projects and activities have been undertaken worldwide to put math on the Web. Moving beyond the assembling of digitized collections of documents into databases with some basic text-search capabilities, recent efforts have focused on: 1. creating standards and software tools for math-content development; 2. developing feature-rich digital libraries of mathematics; and 3. applying the tools and digital libraries to more effective math education and the advancement of math research. For example, XML-based math representation languages for the Web have been developed, most notably OpenMath and MathML, along with major extensions such as OMDOC. Various LaTeX-to-HTML and LaTeX-to-XML conversion tools, such as LaTeXML, have been created, and leading computer algebra systems now provide features for exporting content to MathML. Slated to be released soon is the Digital Library of Mathematical Functions (DLMF), which is a library of thoroughly validated, highly-robust contents, represented in LaTeX and XML, and designed for use in advanced applications of special functions in science, engineering, and other technical disciplines. The DLMF also has a new math-enabled search system for quick and easy access not only to text but also to equations and math expressions.

The focus of this minisymposium is to present to mathematicians and users of mathematics a carefully selected cross-section of the activities, tools, and current practices of putting math on the Web, describe their benefits, and begin to outline a vision of what math on the Web (MOW) will be. The objectives are threefold:

(1) to inform the community at large of the state of the art of MOW technology;
(2) to share with current and future MOW designers and developers the lessons learned from ongoing projects; and
(3) to identify feasible and useful future directions that MOW needs to follow.

Eight of the top leaders and advocates of the MOW field will present talks at this minisymposium.

Utilizing the DLMF in scientific research. **Daniel Lozier** (National Institute of Standards & Technology, USA) IC/MT4971/011

The NIST Digital Library of Mathematical Functions (DLMF) is to be the Web and hard copy successor to the well-known and highly successful NBS Handbook of Mathematical Functions, edited by M. Abramowitz and I. A. Stegun. This talk, by the DLMF General Editor, describes ways in which the Web interface to the mathematical database of the DLMF augments the traditional manner of access to scientific reference information.

Lessons from the trenches: a survey of approaches for large-scale projects. **Robert Miner** (Design Science, Inc., USA) IC/MT1510/011

Large-scale projects play an important role in today's Math on the Web landscape. Technical content is continually being published to the Web in many contexts, ranging from individual educators posting course notes to major science publishers producing online journals. However, for most people, the bulk of useful technical material tends to be in large-scale, ongoing, actively curated collections.

One obvious reason that a large proportion of the most valuable technical content resides in large collections is that publishing technical content is technically challenging. Just as with print, authoring technical documents for the Web requires special software and expertise. Similarly, available display options within Web browsers either involve significant compromise in quality, or a significant increase in technical complexity. Between authoring and display, the workflow processes that ensure high-quality, high-functionality documents add more complexity still, but they also have potential to add value beyond the reach of most small projects. All these factors favor large-scale, ongoing operations where technical expertise can be concentrated and leveraged.

Of the leading large-scale repositories of technical content, most are comparatively old and established. Their technology platforms have evolved alongside XML and Web technology, and now reflect the state of the art. Their production processes have similarly matured. Unsurprisingly, over time, a small number of strategies have emerged as viable choices for the major stages of any Math-on-the-Web workflow: authoring, intermediate processing and display. In this talk, we will survey the strategies employed by a number of leading Math-on-the-Web projects such as Wikipedia, the arXiv, Connexions, the World Math Digital Library, a number of commercial and society publishers, and assorted others.

Extending the Reference Web *using modern TEXniques.* **Ross Moore** (Macquarie University, Australia) IC/MT4972/011

Having ready access to the metadata for scientific papers is important in enabling interested researchers to locate work done by others that is relevant to their own studies. Modern TEX systems can do a lot more than just produce a printable version of a paper suitable for publication. In this talk I will show examples of PDFs of mathematical papers for which the same TEX run produces metadata files in different formats (such as BibTEX, XML, RSS) which are included within the PDF files as attachments. Also the TEX run composes a web-page that displays the metadata, including all the references (á la "Reference Web" recommendations), to fit into a web-site for all articles within a volume issue of the particular journal. This page includes hyperlinks to the MathSciNet database entry for each cited reference, whenever these exist.

One particular advantage of distributing metadata in this way, is that the possibility for mis-spelling (e.g., of the author's name) is reduced, since it has been generated from the same source information used to typeset the article itself. Furthermore, obtaining the MathSciNet entries for cited references is programmed to be done automatically as part of the TEX job. This feature is not 100% reliable, but is easily supplemented by manual searching, and can be suppressed if desired. Other PDF navigation features and effects are included to make the online reading experience much easier; e.g., on a laptop, and for when electronic paper becomes a reality. Among these features are bookmarks (including math-symbols) and hyperlinks to significant parts of the article, moveable pop-up figures, back-references to citations, and use of colour for headings, equation numbers, theorems, definitions, remarks, and such-like.

Discussion of the advantages of these features in other contexts is encouraged. If time permits, methods used to construct the CD and website of abstracts for this ICIAM-07 congress may also be examined.

Content-level mathematics: its usage in learning on the web. **Paul Libbrecht** (DFKI GmbH and Universität des Saarlandes, Germany) IC/MT2439/011

Encoding of mathematical objects and documents can be done at three levels: the presentation level, with TeX or MathML as examples, encodes such constructs as paragraphs, exponents, or rows of operator-symbols and identifiers; the semantic level provides structure to encode the full mathematical meaning of each statement, proof, and expression, hence includes all formal and logical details in a proof or a statement.

content-level mathematics representations encode parts of mathematical documents as a structure of meaningful fragments, such as definitions or motivations and allows for textual parts as well as mathematical formulae using applications, bindings, and named symbols. Mathematical documents at the content-level are much easier to encode and exchange than at the semantic level and they are more interoperable and reusable than presentation-level representations since parts are defined with their mathematical roles.

For many applications the content-level suffices for reuse and interoperability since the additional proof information in which calculus and under which assumptions a theorem has been proved may not be relevant for the application.

The OMDoc language is a content-level encoding, including OpenMath. The ActiveMath learning environment puts this encoding in action, providing strong services which use the knowledge structure encoded.

We shall present an overview of the usage of content-level mathematics as it currently works in ActiveMath, e.g., the cross media formulae presentation, the ability to copy-and-paste formulae, the domain-knowledge structuring the learner-modelling and pedagogically founded content-selection...

Our approach to input of content-level-mathematics will be described. At the heart of the challenges lies the extensibility of the mathematical ontology built by content-level-mathematics. We promote the freedom of authors to define new symbols and concepts as opposed to a central ontology engineering. This brings all kind of problems e.g when the domain-knowledge for the student model is generated from them. These problems are natural and uncover inconsistencies in content which have to be recovered in the authoring process. This freedom also challenges the interoperability with external mathematical systems for which we explore solutions' avenues.

IC/MP263/011: **Math on the web: content development and implementation.** #2
Organiser: Daniel Lozier (National Institute of Standards & Technology, USA)
Co-organiser: Abdou Youssef (The George Washington University, USA)
Co-organiser: Bruce Miller (NIST, USA)

(For abstract, see session #1 above.)

Language technologies for semantic markup in mathematics. **Olga Caprotti** (University of Helsinki, Finland) IC/MT2925/011

In this talk we will report the recent progress obtained in the frame of the Web Advanced Learning Technologies project in applying state of the art language technologies to semantic markup of mathematics for automatically producing renderings of mathematical content in a variety of languages. The intended application of this work is the area of computer assisted assessment and testing in mathematics where can be used to produce, for instance, standardized entry examinations for perspective students to be used independently of country and language. A similar approach can be developed for any situation in which it is possible to identify a specific mathematical jargon.

Respecting implicit semantics in mathematical markup. **Stephen Watt** (University of Western Ontario, Canada) IC/MT3554/011

We present a new strategy for conversion between TEX mathematical expressions and MathML. Previous efforts have attempted either superficial high level transliteration or full execution of TEX. We observe that important semantic concepts are often present in the source markup in the form of macro applications. Our approach is unique in retaining this implicit semantic information as the documents are translated. The translator output may be used immediately by applications, or can be adopted as *replacement source* for on-going work. Our implementation allows control over which macros are expanded and which are mapped at a semantic level.

The principal contributions of this work are:

- A new approach to TEX/MathML translation that conserves and exploits implicit semantics.
- An architecture that allows new representations of semantic information to be associated with existing documents (e.g., association of OpenMath definitions to existing LATEX documents).
- Useful converters from TEX math to MathML and MathML to TEX, and an examination of issues that arise in their implementation.

Creating webs of math using LATEX. **Bruce Miller** (NIST, USA) IC/MT2597/011

How can authors and editors create mathematical content targeted for print and the web, and perhaps uses unforeseen, in a way that takes fullest advantage of each media's capabilities? We will flesh out this question by discussing and contrasting the capabilities and needs of each medium as well as the apparent conflicts. We will highlight some of the possibilities enabled by the web that are unique to mathematical material. After giving a brief overview of the possible answers to the question, we will focus on one tool, LATEXML, that is being used in the Digital Library of Mathematical Functions (DLMF) project. LATEXML converts LATEX sources to an XML format that closely mimics the LATEX document structure and which is easily converted to HTML, images, MathML and other formats. Using LATEX helps solve the print issue. By mimicking LATEX's structure, it helps avoid loosing the author's semantic intent. More interesting, by leveraging TEX's macro capability, on the one hand, and LATEXML's extensibility, on the other, it allows authors to enhance the semantic content, meta-information and document structure to whatever extent is needed. We will illustrate with examples from the DLMF.

Recent advances in Math Search. **Abdou Youssef** (The George Washington University, USA) IC/MT1311/011

As Web repositories and digital libraries of mathematical contents proliferate, one key support service is math-aware search. A math-aware search system should allow users to enter math queries that involve not only text keywords, but also mathematical expressions, expression-fragments, and various mathematical symbols. The system should also *understand* the math contents: symbols and structures, and thus be able to match math queries to math contents.

Several research projects for developing math search techniques and systems have been undertaken in North America and Europe, and even some search systems have been deployed or about to be completed and put into operation. A few of the systems are special purpose, such as table lookups or formal-math search, while others are roughly general purpose, tailored to general math-expression search.

This talk will address the advances made so far in math search. The different approaches will be outlined, a preliminary taxonomy of math search will be put forth, the major issues will be identified, methods for solving them will be discussed, and desirable future directions will be laid out. Achieving math-awareness in search, generation and use of math metadata, context-based math search, hit-relevance measures for math hits, interfacing, benchmarking and performance evaluation of math search systems, and portability of math search software across different math-content formats (LATEX, MathML, OMDOC, etc.), are some of the key aspects of math search that will be the focal points of discussion.

IC/MP218/012: Recent advances in software tools for scientific computing.

Organiser: Ronald Boisvert (National Institute of Standards & Technology, USA)
Co-organiser: Brian Ford (University of Oxford, UK)

Computation has become an indispensable tool for progress in science and engineering. For applied mathematicians and computer scientists who develop mathematical software tools, the central question remains the same as it was in the early days of computing: how should mathematical software be designed to get the highest performance possible, while remaining cost-effective to develop and maintain, as well as easy for users to deploy? The computing landscape today, however, is far different than it was when general purpose electronic computers emerged some 50 years ago. While processors have become cheap and ubiquitous, their underlying computer architectures have actually become more complex. Today such systems have multi-level hierarchical memory systems, multiple processors per chip, special-purpose co-processors, etc. On the Web, emerging service-oriented architectures (computational grids) envision the ad-hoc marshaling of disparate and widely distributed resources to attack computational problems and to share results. At the high end, hundreds to thousands of processors and memory systems are linked together into complex interconnection networks to address society's most challenging problems. Designers of mathematical software libraries, problem-solving environments, and related tools, which provide users with the capabilities needed to efficiently exploit such systems for practical use, are being challenged anew to develop scientific computing tools for this increasingly complex computing landscape. In this minisymposium, we will review how researchers and developers of scientific computing tools are addressing these issues. Speakers will review the state-of-the-art in mathematical software design, including emerging numerical algorithms, software architectures, user interfaces, testing methodologies, as well as some selected applications. (This minisymposium is dedicated to Dr. James C.T. Pool on the occasion of his recent retirement.)

Reflections on progress in software tools for numerical software. **Brian Ford** (University of Oxford, UK), Steve Hague (Numerical Algorithms Group (NAG), UK) IC/MT2403/012

We begin our reflections by considering the question: "What does the term *software tool* mean in the context of numerical software?" The short unhelpful answer to that question is "Different things to different people!". We will try to give a longer and more helpful answer by identifying various software tools which are indicative of the range of such tools, and which could be described as representing landmarks in the evolution of the discipline of numerical software engineering; that is ,the task of designing,developing,testing,documenting,porting and maintaining high quality software for numerically intensive applications. The field of numerical software has advanced significantly over the past forty years or so, and software technology has played a major part in that advance. We anticipate that the importance of such technology will continue in the future,not least in the area of software re-use, a practice long since embraced by the numerical software community but adopted only relatively recently by the world of computing generally. In numerical software terms,re-use means establishing desirable properties, such as robustness and accuracy, of a body of software, and then enabling the reliable and effective use of that software, with those properties intact, in different application or computational contexts. Since we cannot anticipate in all cases what those different contexts might be, this will always be "work in progress", but we will illustrate the progress made so far by referring to the NAG software development regime known as the Library Engine. This so called "engine" draws on numerous prior developments and experiments in software technology both by NAG itself and other numerical software practitioners, not least the pioneering work undertaken at Argonne National Laboratory in connection with the PACK projects, under the leadership of Jim Pool.

Mathematical software and Matlab. **Cleve Moler** (The MathWorks, Inc., USA) IC/MT1129/012

I will reminisce about the (not so recent) role of Jim Pool, Argonne, NAG, IMSL, WG2.5, Caltech, NASCAR, and the Tektronix 4081 in the development of LINPACK, EISPACK and MATLAB.

Recent progress in LAPACK and ScaLAPACK libraries for numerical linear algebra. **Sven Hammarling** (NAG Ltd, UK) IC/MT1569/012

In this talk we shall be looking at recent and forthcoming developments in the widely used LAPACK and ScaLAPACK numerical linear algebra libraries.

Improvements include the following: Faster algorithms with better numerical methods, memory hierarchy optimizations, parallelism, and automatic performance tuning to accommodate new architectures; more accurate algorithms, and the use of extra precision; expanded functionality, including updating and downdating and new eigenproblems; putting more of LAPACK into ScaLAPACK; and improved ease of use with friendlier interfaces in multiple languages.

After an overview, this talk will highlight new more accurate algorithms; faster algorithms, including those for pivoted Cholesky and updating of factorizations; and hybrid data formats. To accomplish these goals we are also relying on better software engineering techniques and contributions from collaborators at many institutions.

This is joint work with Jim Demmel, Jack Dongarra and the LAPACK/ScaLAPACK team.

The challenges of multicore and specialized accelerators for mathematical software. **Jack Dongarra** (Univ. Tennessee & Oak Ridge National Lab, USA) IC/MT1128/012

Recent versions of microprocessors exhibit performance characteristics for 32 bit floating point arithmetic (single precision) that is substantially higher than 64 bit floating point arithmetic (double precision). Examples include the IntelŠs Pentium IV and M processors, AMDŠs Opteron architectures, the IBMŠs Cell processor and various GPUs. When working in single precision, floating point operations can be performed up to two times faster on the Pentium and up to ten times faster on the Cell over double precision. The motivation for this work is to exploit single precision operations whenever possible and resort to double precision at critical stages while attempting to provide the full double precision results. The results described here are fairly general and can be applied to various problems in linear algebra such as solving large sparse systems, using direct or iterative methods and some eigenvalue problems. There are limitations to the success of this process, such as when the conditioning of the problem exceeds the reciprocal of the accuracy of the single precision computations. In that case the double precision algorithm should be used.

IC/MP218/012: Recent advances in software tools for scientific computing. #2

Organiser: Ronald Boisvert (National Institute of Standards & Technology, USA)
Co-organiser: Brian Ford (University of Oxford, UK)

(For abstract, see session #1 above.)

The evolution of software for computational optimization. **Jorge Moré** (Argonne National Laboratory, USA) IC/MT3500/012

We outline and discuss developments in computational optimization that have changed the way that large nonlinear optimization problems are formulated, analyzed, and solved. These developments include sophisticated algorithms and software, automatic differentiation tools, mathematical programming languages, and high-performance (parallel) architectures. The aim of these developments is to expand the range and size of optimization problems that can be modeled and solved by application scientists. We outline and discuss these developments in the context of our experiences with TAO (Toolkit for Advanced Optimization).

A test harness (TH) for high-performance numerical software. **Brian Smith** (University of New Mexico, USA) IC/MT1796/012

TH is a test harness to facilitate the development of scientific software. The operational model of the tool is the comparison of the results from two versions of an application code to ensure the results are equivalent. TH is first installed into an existing application code that runs to completion on a set of data. The application code with TH installed is run in generate mode to create a monitored data file. A second version of the application code with TH installed is run in check mode, comparing the current results with the original results, using criteria that tolerate expected rounding errors in the computation.

Features include specifiable criterion for data comparison,

process-independent check data formats, and a design that facilitates the installation of TH into codes written in any programming language and in parallel SPMD codes. Once installed, TH can be deactivated, permitting the same code to be maintained with and without the test harness in use.

A recent enhancement to TH is the implementation of a new set of tools installs TH into a Fortran application code with one of two default TH input files. One default file causes the test harness to monitor the execution sequence through specified procedures of the application and provide performance information for these procedures. The second default file specifies that the test harness monitors all Sexternal T variables of all selected procedures in the application at all entry points to and exit points from the specified procedures. An Sexternal T variable is defined to be any dummy argument, any variable accessed from a common block, or any variable accessed from a module. These default input files can be readily changed to specify the non-default comparison criteria.

Special functions, reference data and mathematical software. **Ronald Boisvert** (National Institute of Standards & Technology, USA) IC/MT1089/012

The Handbook of Mathematical Functions (Milton Abramowitz and Irene Stegun, eds.), a reference work published by the US National Bureau of Standards, remains the most cited work in the mathematical literature more than 40 years after its appearance in 1964. An important application of the Handbook has been in the development of tests for function evaluation software. NIST, in collaboration with some 40 external researchers, is developing the Digital Library of Mathematical Functions (DLMF), a new, Web-based handbook on the special functions of applied mathematics. Presenting such information in a way that is not only natural and convenient in a Web environment, but also provides capabilities that exceed what is available using traditional publication methods, remains a technical challenge. In this talk I will provide background on the DLMF project, with particular attention to the information technology issues related to the presentation of mathematics on the Web. A demonstration of DLMF facilities will be presented. Finally, applications to mathematical software development and testing will be described.

Evolution of mathematical software. **James Pool** (Prescott, Arizona, USA) IC/MT1625/012

The development and distribution of mathematical software has gone full circle in the last forty years. During the 1960s, mathematical routines were developed primarily by users and often contributed to collections accessible to other users. During the following two decades, a community of mathematical software developers emerged and focused on the creation of quality collections and libraries. However, during the past fifteen years, there has been a steadily increasing return to the approach of the 1960s. Why? We will review this evolution of the development and distribution of mathematical software, assess both the technical and non-technical causes of changing modes, and speculate on the future of mathematical software activities.

IC/MP311/012: High-level software for the numerical solution of partial differential equations.

Organiser: Robert Kirby (Texas Tech University, USA)
Co-organiser: Guido Kanschat (Texas A&M University, USA)
Co-organiser: Wolfgang Bangerth (Texas A&M University, USA)

The last decade has seen tremendous growth not only in raw computational power, but also in the sophistication of software for numerical computing. By providing high-level interfaces to powerful, mathematically robust methods such as finite elements, modern libraries greatly simplify and shorten the computational scientist's development cycle, improve productivity, and increase code reliability, frequently without a sacrifice of performance. All of these libraries to some extent provide support for structured or unstructured meshes, basis functions, and interfaces to powerful algebraic solvers. Some also include high-level support for variational forms, by which the algebraic systems are generated automatically from computational objects representing the variational problem. The speakers in this minisymposium will be the authors of several of these software libraries, and they will describe the design philosophy and capabilities of their codes. This minisymposium will allow developers of such codes to exchange ideas and potential users to gain a high-level introduction to emerging tools.

deal.II: a general-purpose object-oriented finite-element library. **Guido Kanschat** (Texas A&M University, USA), Wolfgang Bangerth (Texas A&M University, USA) IC/MT316/012

An overview of the software design and data abstraction decisions chosen for deal.II, a general-purpose finite element library written in C++, is given. The library uses advanced object-oriented and data encapsulation techniques to break finite element implementations into smaller blocks that can be arranged to fit users requirements. Through this approach, deal.II supports a large number of different applications covering a wide range of scientific areas, programming methodologies, and application-specific algorithms, without imposing a rigid framework into which they have to fit. A judicious use of programming techniques allows us to avoid the computational costs frequently associated with abstract object-oriented class libraries.

The paper presents a detailed description of the abstractions chosen for defining geometric information of meshes and the handling of degrees of freedom associated with finite element spaces, as well as of linear algebra, input/output capabilities and of interfaces to other software, such as visualization tools.

Parallel representation of topological data. **Dmitry Karpeev** (Argonne National Laboratory, USA) IC/MT1466/012

We have developed a flexible and scalable high-level framework for representation of topological data, such as, but not limited to, computational meshes, multigrid structures, high-degree graphs, networks, etc.

The novel feature of the approach is that the topological data, called Sieves, are treated with a minimal and flexible interface deriving in spirit from the formalism of cell complexes in combinatorial topology. Thus, the main relation of incidence is generalized in the spirit of Grothendieck to a single "covering" relation between entities in the Sieve. We identify the correct computational analog of such minimal topologies based on *operations* allowable Sieves, rather than attempting to mimic the formal mathematical structure. The minimal operations include 'closure', 'star', 'meet' and 'join', essentially in the same sense as for cell complexes but with a wider range of applicability, enabling navigation of the data.

While in traditional computational approaches the numerical data are inextricably linked to the topological data, we explicitly separate the two. Any Sieve can support *fields* - numerical data laid out over it regardless of the semantics (mesh coordi-

nates, physical fields etc). The ubiquitous domain decomposition approach is recognized as an instance of the *sheaf* property of fields, and implemented in a fashion appropriate for computational use. Specifically, we allow collections of Sieves (e.g., distributed among processors) to be related with an *overlap* Sieve. Fields can then be restricted to the overlap from individual Sieves as well as fused along the interface.

We will present the framework and illustrate its use in a range of scientific codes.

Automated solution of differential equations. **Anders Logg** (Simula Research Laboratory, Norway) IC/MT435/012

Differential equations are solved routinely by large computer programs, but the solution process is rarely automated. Each equation requires a different program and each such program requires a considerable amount of work to develop and maintain.

The FEniCS project provides a set of tools that automate important aspects of the solution process, ultimately aiming at a complete automation of computational mathematical modeling, including the automation of discretization, discrete solution, error control, modeling and optimization. A key component of FEniCS is the FEniCS Form Compiler (FFC), which automates the discretization of differential equations by taking as input a variational problem in mathematical notation and generating highly efficient optimized low-level code for the evaluation of the corresponding discrete operator.

In this talk, I will discuss key aspects and features of the FEniCS project and give a demonstration by specifying and solving a couple of standard differential equations.

Computing finite-element basis functions. **Robert Kirby** (Texas Tech University, USA) IC/MT1277/012

Access to general families of finite-element basis functions for H^1, $H(\mathrm{div})$, and $H(\mathrm{curl})$ of general order adds great value to the various high-level codes for meshes, solvers, and variational forms. I will talk about some recent developments for FIAT, the FInite element Automatic Tabulator. These include algebraically generating improved algorithms for evaluating functions at quadrature points.

IC/MP311/012: High-level software for the numerical solution of partial differential equations. #2

Organiser: Robert Kirby (Texas Tech University, USA)
Co-organiser: Guido Kanschat (Texas A&M University, USA)
Co-organiser: Wolfgang Bangerth (Texas A&M University, USA)

(For abstract, see session #1 above.)

GetDP: a general finite-element solver for the de Rham complex. **Christophe Geuzaine** (Université de Liège, Belgium) IC/MT1318/012

We present an overview of the structure of GetDP, an open-source software system started ten years ago with the goal of providing a high-level mathematical tool to solve partial differential equations using finite element-type techniques. The main feature of the software is the closeness between the organization of data defining a discrete problem (written by the user in an ASCII text file) and the symbolic mathematical expression of this problem. We show how the high-level decomposition of the problem into a limited number of objects makes the environment structured and concise, and permits the easy coupling of physical problems (electromagnetic, thermal, mechanical, etc.) and numerical methods, in various dimensions and time states.

This is joint work with Patrick Dular at the University of Liège.

FreeFem++, 2D finite-element PDE solver. **Frédéric Hecht** (Université Pierre et Marie Curie, France) IC/MT2143/012

Fruit of a long maturing process freefem, in its last avatar, FreeFem++, is a high-level integrated development environment (IDE) for numerically solvIng partial differential equations (PDE). It is the good tool for teaching the finite element method but it is also perfect for research to quickly test new ideas or multi-physics and complex applications.

A partial differential equation is a relation between a function of several variables and its (partial) derivatives. Many problems in physics, engineering, mathematics and even banking are modeled by one or several partial differential equations.

FreeFem++ is a software to solve these equations numerically. It is not a package, it is an integrated product with its own high level programming language . This software runs on unix, Windows and MacOS X.

Moreover FreeFem++ is highly adaptive. Many phenomena involve several coupled system, for example: fluid-structure interactions and ocean-atmosphere problems are such systems. These require different finite element approximations degrees, possibly on different meshes. Some algorithms require data interpolation on multiple meshes within one program.FreeFem++ can handle these difficulties, i.e. *arbitrary finite element spaces on arbitrary bidimensional meshes*.

FreeFem++ has an advanced automatic mesh generator, capable of *a posteriori* mesh adaptation; it has a general purpose elliptic solver interfaced with fast algorithms such as the multi-frontal method UMFPACK. Hyperbolic and parabolic problems are solved by iterative algorithms prescribed by the user with the high level language of FreeFem++. It has several triangular finite elements, including discontinuous elements. Finally everything is there in FreeFem++ to prepare research quality reports: color display online with zooming and other features and postscript printouts.

The web site is http://www.freefem.org/ff++

A modern and unified C++ implementation of finite-element and spectral-elements methods in 1D, 2D and 3D: overview and applications. **Christophe Prudhomme** (Université Grenoble I, France) IC/MT3504/012

We present in this talk a modern and unified C++ implementation of finite and spectral element methods in 1, 2 and 3D that provides a mathematical kernel for a number of complex multiphysics and multiscale simulations, such as fluid structure interaction or mass transport, in the context of haemodynamics. The main result consists of a library of components that provides domain-specific abstractions, in our case numerical analysis tools, using generic, meta-programming and object-oriented paradigms. At the top of these components sits a so-called domain-specific language embedded in C++ that allows to formulate variational problems in terms close to the mathematics. This has a number of advantages among which high-level expressivity and using implicitly the properties of the C++ compilers such as their optimization framework and their programming environments — preprocessor, libraries... — We shall demonstrate this kernel through applications in blood flow and multi-fluid flow simulations.

IC/MP125/012: Image processing: computation and applications.

Organiser: Choi-Hong Lai (University of Greenwich, UK)
Co-organiser: Meiqing Wang (Fuzhou University, PR China)

There are many applications of image processing in industry and also for personal leisure. Examples include media applications, video on demand, archive management, digital library, underground-piping recognition/examination, crack location, groundwater flow, soil properties, image restoration for historical heritage, image de-blur, image impainting, etc. Many of these examples require fast computer hardware and good numerical methods to reach industrial standards. Researchers from the major fields of mathematics and computer science are required to collaborate in order to achieve the best results. This mini-symposium provides a forum for scientists and practitioners, in the main areas of mathematics, computer science, and image processing to exploit and enhance techniques for image processing making them viable for industrial applications. The theme of the mini-symposium concerns all aspects of image processing, including image compression, image de-noising, image restoration, parallel processing, and their industrial applications. Use of partial differential equations will be examined for image de-noising, image de-blur, and image impainting. Use of fractals and wavelets for image compression and de-compression will be examined for video and archive applications. State-of-the-art parallel algorithms for image processing are also included in the dissemination.

Video compression using fractal and color-transfer algorithm. **Meiqing Wang** (Fuzhou University, PR China), Sihui Chen (Fuzhou University, PR China), Choi-Hong Lai (University of Greenwich, UK) IC/MT480/012

Recently many methods for achieving high compression ratios in video compression have appeared in literature and in the industry, including MPEG, H.263, JPEG, wavelets and fractals. Among these methods, the fractal method is a feasible and promising compression technique due to its low complexity in the process of decompression and high compression ratio. Handling colour images using fractals is important in the digital images and human visual system because colour images are almost indispensable for human perception. In the study of color images, color transfer algorithms are usually used to convert an image's colors which lead the conversion of the image's scene. In this paper we use color transfer technology in fractal video compression to obtain a high compression ratio. As used in other fractal methods, a given sequence of images is divided into groups of frames (about four or five frames in a group). The first frame of each group is compressed by an efficient fractal color image compression method. The remaining frames of the group are converted into gray images, which are then compressed using the adaptive fractal gray image compression method. During the process of decompression, the first frame is decompressed using the corresponding decompression method. For the remaining frames of the group, the corresponding fractal gray video decompression method is used to obtain the gray image sequence, and the sequence is then converted to color ones using the color transfer algorithm by passing the colors of the first frame to the remaining ones of the group. In the experiments two different color transfer algorithms are applied to some video frames. Experimental results show that the algorithm not only is able to obtain a high reconstruction quality (the PSNR value of the decompression video images are about 30), but also can achieve a high compression ratio (above 30) without perceptible image degradation.

Exploiting statistical properties of wavelet coefficient for face detection and recognition. **Naseer Aljawad** (The University of Bukingham) IC/MT495/012

Wavelet transforms (WT) are increasingly becoming an essential tool for image processing and analysis. Image and video compression, image watermarking, content-base image retrieval, face recognition, texture analysis, and image feature extraction are all but few examples. The Wavelet Transform is a technique for analyzing finite-energy signals at multi-resolutions. It provides an alternative tool for short time analysis of quasi-stationary signals, such as speech and image signals, in contrast to the traditional short-time Fourier transform. The Discrete Wavelet Transform (DWT) is a special case of the WT that provides a compact representation of a signal in the time and frequency domain. In particular, wavelet transforms are capable of representing smooth patterns as well anomalies (e.g., edges and sharp corners) in images. In this presentation, we are focusing using wavelet transforms for facial feature detection.

There are a number of different wavelet image-decomposition schemes. The most commonly used scheme is the pyramid scheme, which we have adopted. At a resolution depth of k, the pyramidal scheme decomposes an image I into $3k+1$ frequency subbands $(\mathrm{LL}_k, \mathrm{HL}_k, \mathrm{LH}_k, \mathrm{HH}_k, ..., \mathrm{HL}_1, \mathrm{LH}_1, \mathrm{HH}_1)$. the lowest-pass subband LL_k representing the k-level resolution approximation of the image I, while the other high-frequency sub-bands highlight the significant image features at different scales. Interestingly, the histogram of the LL sub-band is an approximation of that of the original image, while the coefficients in each of the other subbands have a Laplacian (also called generalised-Gaussian) distribution. In this presentation we shall review various techniques that exploit the statistical properties and parameters of the non-LL sub-bands to locate and detect faces in images/videos. We shall present test results to measure the performance of these techniques using bench-marked audio-visual images/video.

MPEG-4 video transmission over UMTS mobile networks. **Maaruf Ali** (Oxford Brookes University, UK) IC/MT679/012

This talk will present an overview of MPEG-4, covering the structure of MPEG-4 coded video files and the VOP types. Followed by classification of errors and introduction of the NEWPRED mechanism in MPEG-4 for error concealment. An UEP (Unequal Error Protection) scheme will also be described ending with how the application of the proposed scheme is used in quanitifying improvements in the UMTS network efficiency.

Application of the topological gradient to image processing. **Mohamed Masmoudi** (Université Paul Sabatier Toulouse III, France) IC/MT947/012

The goal of most image processing problems is to split the image in several parts. This is the case of classification, segmentation and edge detection problems.

To find a part of an image is equivalent to find its characteristic function. At first sight this problem is not differentiable, but using calculus of variation methods, it is possible to derive the variation of a cost function when we switch the characteristic function from 0 to 1 or from 1 to 0 in a small area. This variation is called the topological gradient.

This gradient type information allows to build very fast algorithms. In most applications the solution is obtained in only one iteration.

We first recall the basic concept of topological gradient and its applications to optimal design and imaging. Then we con-

sider some image processing problems under the topological gradient point of view.

We present its application to edge detection, by inserting small cracks in the image. The restoration of noisy images is then pretty straightforward. Some restorations of short video sequences will be presented.

To restore hidden parts of an image (inpainting), the edges (or cracks) of the known image are propagated inside the hidden part. The restoration is done using diffusive approaches taking into account the insulating edges.

IC/MP125/012: Image processing: computation and applications. #2

Two-phase methods for deblurring images corrupted by impulse plus Gaussian noise. **Raymond Chan** (Chinese University of Hong Kong) IC/MT140/012

We consider the problem of restoring blurred images which are corrupted by impulse noise and possibly Gaussian noise. We solve the problem in two phases. In the first phase, median-type filters are applied to locate the pixels which are likely to be corrupted by impulse noise. In the second phase, we solve an inverse problem from incomplete data by a variational method. More precisely, we minimize a regularized functional involving only the data samples detected as outlier-free in the first phase. The experiments show that our method is 4–7 dB better in PSNR than a full variational methods for image deblurring under impulse noise. Moreover, our scheme can restore blurred images corrupted by 90% salt-and-pepper noise or 50% random-valued impulse noise.

Parallel computing algorithms and CAGD processing methods for fractal images in virtual geographic environments. **Dan Liu** (Dalian Maritime University, PR China) IC/MT154/012

This talk starts with the theory and applications of Nonlinear Mathematics, develops the research on basic theory and methods of geographic Fractal model computing in virtual geographic environment with very strong applying background, establishes scientific parallel computing model, designs more effective parallel computing algorithm of geographic Fractal models. After exploiting and founding common parallel landscape simulation theory, combines the related techniques and methods of Fractal, Wavelet and CAGD(Computer Aided Geometric Design), constructs high dimensional Fractal algorithm, synchronic Fractal display algorithm of 3D multi-channel scene, texeture synthesizing algorithm based on shape surfaces etc. As we all known, the Fractal simulation technique can achieve high fidelity when it is used to simulate nature scenery, the main drawback of such techniques is the very high computing time needed to determine the realtime display;in addition, the key actual physiognomy simulation technique CAGD is not very good at dealig with 3D nature anomalistic objects. The talk will also introduce some research on parallel computing of geographic Fractal models, including correlative system configuration, parallel algorithm and parallel programme, the shown results have improved the fidelity of mutual simulation system and the generating speed of Fractal images greatly, produced complicated 3D physiognomy simulation with arbitrary distinguished degree, and altered the states of the simulated entities dynamically.

Bilinear interpolation for image conversion between square structure and hexagonal structure. **Xiangjian He** (University of Technology, Sydney, Australia) IC/MT387/012

Spiral Architecture (SA) is a relatively new and powerful approach to machine vision system. The geometrical arrangement of pixels on SA can be described as a collection of hexagonal pixels. However, all the existing hardware for capturing image and for displaying image are produced based on rectangular architecture. Therefore, it becomes important to find a proper software approach to mimic SA so that images represented on the traditional square structure can be smoothly converted from or to the images on SA. For accurate image processing, it is critical to best maintain the image resolution during the image conversion. In this paper, we present an algorithm for bilinear interpolation of pixel values for image conversion between square structure and the simulated SA. The comparison in terms of representation accuracy is performed and demonstrated using experimental results.

Gradient-field computation and its application in image inpainting. **Choi-Hong Lai** (University of Greenwich, UK), Meiqing Wang (Fuzhou University, PR China), Xunxun Zeng (Fuzhou University, PR China) IC/MT462/012

The task of filling in missing or damaged regions of an image is known as image inpainting which has many important applications in the area of digital image processing. The BSCB model proposed by Bertalmio et al., pioneered a digital image inpainting algorithm based on partial differential equations (PDEs). The basic idea is to smoothly propagate information from the surrounding areas in the isophote directions. A new method for computing the gradient field combined with a max/min function is proposed as the information propagating estimator to improve the BSCB model. Since the above improved method provides good results at corners, it is also applied to the Euler's elastica model. Numerical experiments show that the modified methods can repair the images well, especially along edges and at corners.

IC/MP86/012: Writing scientific software: experience with using, developing and teaching.

Organiser: Osni Marques (Lawrence Berkeley National Laboratory, USA)
Co-organiser: Suely Oliveira (The University of Iowa, USA)

Writing scientific software requires attention to both numerical and software engineering aspects. Performance trade-offs in using modern programming languages and systems can be difficult to understand, but are crucial for many applications. While the basic development of new ideas can be implemented using basic interactive tools, at the high-performance edge, software has to be carefully designed, documented, and tuned for future updates.

In this minisymposium we bring together speakers from National Labs and academia who work with numerical and software aspects of scientific programming. We will emphasize experience in using, developing and teaching scientific software.

Scientific programming as a science. **Paolo Bientinesi** (Duke University, USA), Robert van de Geijn (University of Texas at Austin, USA), Enrique Quintana-Orti (Universitat Jaume I, Spain) IC/MT249/012

In recent years it has become customary to use clusters of hundreds of computers for running large scientific computations. The programming paradigm was that of distributed memory parallel systems. With the advent of SMP and multi-core systems, we are now moving towards hybrid platforms in which distributed memory and shared memory paradigms live together. Multi-core systems with dozens of cores may become the norm within a decade. Writing and tuning high-performance software in such environments is challenging. Besides, in order to attain maximum performance, additional algorithms, with respect to the ones commonly used in a sequential environment, will have to be developed. This further increases the burden on the programmers.

In this talk we show how a high-level notation and a goal-oriented approach can be used to systematically develop high-performance linear algebra libraries. These libraries contain several algorithms for each target operation and can be created in a number of target languages. The methodology, developed as part of the FLAME project at UT-Austin, is powerful enough to create libraries like LAPACK, yet simple enough that it can, and has been, taught at the undergraduate level. The key is to approach high-performance programming with rigorous tools from computer science as opposed to ad-hoc methods.

Life as a developer of numerical software. **Sven Hammarling** (NAG Ltd, UK) IC/MT251/012

Rewards of readily-available software tools. **Leroy Anthony Drummond-Lewis** (Lawrence Berkeley National Laboratory, USA), Osni Marques (Lawrence Berkeley National Laboratory, USA) IC/MT1756/012

The US Department of EnergyŠs (DOE) Advanced Computational Software (ACTS) Collection comprises a set of software tools that make it easier for application developers to write high performance codes for high-end computers. The development of such codes is often a demanding process, due to the complexity of the phenomena to be simulated but also to the proliferation and evolution of computer architectures. ACTS tools have lessened the development effort in a number of cases, and also contributed for an optimal usage of the available, and often scarce, computational resources. The tools fall into four broad categories: implementation of numerical algorithms, frameworks, execution support and developer support. This presentation will focus on the functionalities currently available in the collection; lessons that have been learned through an interaction with tool developers and; the rewards of outreach efforts and hands-on activities; and scientific applications that have benefited from the tools.

Scientific programming and object-oriented approaches, with emphasis on multigrid software. **Ricardo Ortiz** (University of Iowa, USA), Suely Oliveira (The University of Iowa, USA) IC/MT1975/012

Many problems in scientific computing require a large amount of computations. The reason for this may be because the problem requires or produces large amounts of data or simply because of the problem's complex nature. For this reason we need to write scientific code that is easy to read, reusable and at the same time performs computations accurately and efficiently. Ever since the 1950s, the complexity of scientific software has been increasing. Object oriented techniques have been developed to alleviate this complexity and now more people are writing scientific software in C and C++ like languages. We present a multilevel algorithm framework written in C++ for solving large scale linear system of equations and discuss some of the programming techniques used to improve code readability and achieve peak performance. The design of the framework is separated into a series of modules that allow us to debug the code faster and test its performance in an easy and systematic way.

IC/MP221/012: Combinatorial scientific computing.

Organiser: Alex Pothen (Old Dominion University, USA)

Combinatorial scientific computing (CSC) is an interdisciplinary research area in which combinatorial mathematics and algorithms are employed to solve problems in scientific computing. While research in CSC has been ongoing since the 1970's, the CSC research community has been fragmented because the myriad roles of combinatorial methods are scattered in standard taxonomies of scientific computing. In order to address this fragmentation, the CSC community has organized three international workshops since 2004, two of them sponsored by SIAM. This minisymposium affords an opportunity for members of the CSC community to interact with the global applied mathematics community.

The eight speakers in this minisymposium will discuss recent research on a collection of CSC topics. Among these are: graph matching models and algorithms for computing good orderings for factoring sparse matrices; support theory methods for computing novel, combinatorial preconditioners for solving sparse linear systems of equations; hypergraph partitioning for load-balancing in parallel computing; combinatorial problems in automatic differentiation; specialized graph coloring problems and coloring algorithms to efficiently compute large-scale Jacobians and Hessians; practical parallel algorithms for combinatorial problems on massively parallel computers, etc.

Developments in matching and scaling algorithms. **Iain Duff** (Rutherford Laboratory & CERFACS, UK) IC/MT3235/012

For many years the HSL code MC64 developed by Duff and Koster (SIMAX 22 pp.973–996) has been used primarily as a preprocessing step for both iterative and direct solvers. We discuss enhancements to this code and, in particular, examine its use in predetermining pivot sequences for symmetric indefinite factorization. We demonstrate its use as an analysis tool with the HSL symmetric indefinite code MA57. This work is based on joint work with Stephane Pralet, Samtec, Liege, Belgium. We also illustrate how a similar approach can be used in a code for the direct solution of sparse skew symmetric matrices.

An option in MC64 provides a scaling so that the scaled system can be permuted so that the diagonal has value one and all off-diagonal entries are less than or equal to one in modulus. We compare the effect of using this scaling compared with a scaling that tries to make all entries close to one and another that makes the scaled matrix doubly stochastic. We compare these approaches both in the context of direct and iterative solvers.

Matching algorithms in scientific computing. **Florin Dobrian** (Old Dominion University, USA), Mahantesh Halappanavar (Old Dominion University, USA), Alex Pothen (Old Dominion University, USA) IC/MT2933/012

We discuss the combinatorial optimization problem of graph matching in the context of scientific computing. Matching has a special place among combinatorial optimization problems because, although not ubiquitous, it can be solved optimally in polynomial time. Therefore, from a theoretical perspective, matching algorithms are considered to be efficient.

In practice, however, polynomial time complexity is not necessarily equivalent to efficiency. The time complexity of matching algorithms is actually superlinear and it may take too long to compute a matching in a very large graph. In order to address this issue one can attempt either to employ fast approximation algorithms, which compute suboptimal solutions, or to rely on parallelization. However, exact matching algorithms, i.e., matching algorithms that compute optimal solutions, tend to be difficult to parallelize and parallelization may have to rely on approximation as well in high performance matching codes.

One area with a strong emphasis on high performance is scientific computing, where advanced scientific problems are simulated on highly sophisticated supercomputers. Graph matching can be used in scientific computing as a technique for modeling various sparse matrix computations, which represent basic scientific computing tools. In this talk we present new efficient modeling techniques for sparse matrix computations that are based on graph matching algorithms, the algorithms employed being both exact and approximation. Through theoretical and experimental results we show that the new techniques can outperform those that were previously used in modeling sparse matrix computations.

Hierarchical coloring. **Paul Hovland** (Argonne National Laboratory, USA) IC/MT4198/012

Discretizing PDEs on a regular grid induces a hierarchy of two types of sparsity patterns on a Jacobian matrix, one due to the stencil being used and one due to the dependence among individual degrees of freedom within that stencil. Goldfarb and Toint demonstrated how to exploit the sparsity structure induced by the stencil, but exploiting the unstructured sparsity within the stencil must rely upon more general techniques. We present a two stage coloring strategy: Goldfarb-Toint coloring followed by optimal intra-stencil coloring. We demonstrate that optimal coloring at both stages is suboptimal in general. Nonetheless, savings of 50% or more over Goldfarb-Toint alone are possible.

Computing Hessians without tears: automatic differentiation and graph coloring. **Alex Pothen** (Old Dominion University, USA) IC/MT4153/012

Interior-point methods for nonlinear optimization problems require second-order derivatives of the Lagrangian function, and exact Hessians are needed in parametric sensitivity analysis. A sparse Hessian matrix can be computed accurately using automatic differentiation via a three-step procedure. First, using the nonzero pattern of a Hessian, we partition its columns into groups, such that the nonzeros in the columns of a group can be computed together. Second, we compute the numerical values of the nonzeros in each group of columns in the partition by automatic differentiation. Finally, we recover the values of the nonzeros in the Hessian from the values in the groups in the partition. The first step is accomplished by a specialized graph coloring: a star coloring, if the nonzero values in the Hessian are computed by solving a diagonal system of equations; or an acyclic coloring, if the nonzeros are computed by solving a triangular system of equations. We describe new algorithms for the first and third steps, and integrate our codes with ADOL-C, a software tool for automatic differentiation. Our results show that evaluating a Hessian via a triangular substitution method using acyclic coloring is currently the fastest method, and that this approach makes the computation of Hessians with hundreds of thousands of columns feasible.

Combinatorial preconditioners for scalar elliptic finite-element problems. **Haim Avron** (Tel Aviv University, Israel), Gil Shklarski (Tel Aviv University, Israel), Sivan Toledo (Tel Aviv University, Israel) IC/MT2852/012

We present a new preconditioner for linear systems arising from finite-elements discretizations of scalar elliptic partial differential equations (PDE's). The linear system is denoted $Kx = b$, where K is the global stiffness matrix and is a sum $K = \sum_e K_e$ of element matrices. The solver splits the collection $\{K_e\}$ of element matrices into a subset $E(t)$ of matrices that are approximable by diagonally-dominant matrices and a subset of matrices that are not approximable. The approximable K_e's are approximated by diagonally-dominant matrices L_e's that are scaled and assembled to form a global diagonally-dominant matrix $L = \sum_{e \in E(t)} \alpha_e L_e$. A combinatorial graph algorithm approximates L by another diagonally-dominant matrix M that is easier to factor. The inapproximable elements are added to M and the sum $M + \sum_{e \notin E(t)} K_e$ is factored and used as a preconditioner. When all the element matrices are approximable, which is often the case, the preconditioner is provably efficient. Experimental results show that on some problems, the preconditioner is more effective than an algebraic multigrid solver, than an incomplete-factorization preconditioner, and than a direct solver.

Hypergraphs in scientific computing. **Rob Bisseling** (Universiteit Utrecht, The Netherlands) IC/MT2391/012

In the past decade, hypergraphs have emerged as a powerful tool in scientific computing applications. Hypergraph partitioning is the method of choice for distributing the data for sparse matrix–vector multiplication in an iterative linear system solver, or in a parallel computation of the PageRank eigenvector, which represents the ranking of web pages. Hypergraph clustering can be used to find related documents in large text collections, or in biological data sets.

This talk gives a survey of current and potential hypergraph applications, and discusses the use of the Mondriaan matrix partitioning package as a more general hypergraph tool. Furthermore, it presents recently added features such as scaled inner product matching, hybrid Mondriaan–fine grain partitioning, and a MATLAB interface.

Combinatorial models and algorithms for parallel sparse matrix distributions. **Erik Boman** (Sandia National Laboratories, USA) IC/MT2566/012

Sparse matrix-vector multiplication is an important kernel in scientific computing. This is the core of iterative linear solvers. For parallel computing, reducing the communication is crucial. This is a rich combinatorial problem. We first review classic graph and hypergraph models for sparse matrix partitioning, and then present new models for 2d fine-grain matrix partitioning. We discuss graph algorithms for our new approach. Preliminary results will be presented.

Hypergraph-based dynamic load-balancing for adaptive scientific computations. **Ümit Çatalyürek** (The Ohio State University, USA), Karen Devine (Sandia National Laboratories, USA), Erik Boman (Sandia National Laboratories, USA), Doruk Bozdağ (The Ohio State University, USA) IC/MT2585/012

Load-balancing (also known as *partitioning*) is a critical component in parallel scientific computing to achieve higher degree of parallelism. The goal is to assign computation to processors evenly while trying to minimize the communication volume. This assignment occurs at the start of a computation (*static* partitioning), but often, reassignment of work is done during a computation (*dynamic* partitioning) as the work distribution changes over the course of a computation. Hypergraph-based load balancing has proved to be successful for static load balancing problem in scientific computations, and partitioning software for the static case is widely available. In this talk, we present a new hypergraph model for the dynamic case, where we minimize the sum of communication in the application plus the migration cost to move data, thereby reducing total execution time. The new model can be solved using hypergraph partitioning with fixed vertices. We describe an implementation of a parallel multilevel partitioning algorithm within the Zoltan load-balancing toolkit, which to our knowledge is the first code for dynamic load balancing based on hypergraph partitioning. Finally, we present experimental results that demonstrate the effectiveness of our approach.

IC/MP172/014: The role of scale and orientation in mathematical image analysis.

Organiser: Arjan Kuijper (RICAM Linz, Austria)

Image analysis is concerned with analyzing the contents of images without *a priori* knowing them. Methods performing this task are usually validated by human observers. Challenging tasks are therefore to define mathematical models that mimic the human brain, and to understand them. The latter requires knowledge of various mathematical fields, like topology, geometry, PDEs, singularity theory, and statistics.

In this mini-symposium requirements for such methods, like scale and orientation of objects are discussed. The mathematical properties of these so-called *scale-space* methods are exploited. This results in models that capture essential characteristics of images. They allow, for instance, a simpler representation, enhancing, and reconstruction of an image. The speakers in this mini-symposium have a strong background in image analysis based on scale-space methods. They will present the current state-of-the-art for these approaches.

Image analysis using p-Laplacian and geometrical PDEs. **Arjan Kuijper** (RICAM Linz, Austria) IC/MT767/013

Minimizing the integral $\int_\Omega |\nabla u|^p \mathrm{d}\Omega$ for an image u under suitable boundary conditions gives PDEs that are well-known for $p = 1, 2$, namely Total Variation evolution and Laplacian diffusion (also known as Gaussian scale space and heat equation), respectively. Without fixing p, one obtains a framework related to the p-Laplace equation. The partial differential equation describing the evolution can be simplified using gauge coordinates (directional derivatives), yielding an expression in the two second order gauge derivatives and the norm of the gradient. Ignoring the latter, one obtains a series of PDEs that form a weighted average of the second order derivatives, with Mean Curvature Motion as a specific case.

Both methods have the Gaussian scale space in common. Using singularity theory, one can use properties of the heat equation (namely. the role of scale) in the full (Ω, t) space and obtain a framework for topological image segmentation.

The general frameworks will be presented and its properties discussed. The relations with gauge coordinate descriptions of the PDEs are shown, as well as filtering properties of solutions of some of these PDEs. Also examples of its use in image evolution and analysis will be given. Relations with the other talks in this mini-symposium will be pointed out.

Coarse-to-fine partitioning of signals. **Luc Florack** (Technische Universiteit Eindhoven, The Netherlands) IC/MT1440/013

We introduce the multiscale extension of a positive, real-valued signal $f(x)$,

$$u(x,s) = \exp\left(s\, d^2/dx^2\right) f(x)\,,$$

and the auxiliary signal

$$g(x,s) = \frac{1}{2}\, u_x^2(x,s)\,.$$

We write $u_0^{(k)}$ for a k-th order x-derivative at $(x,s)=(0,0)$, and assume $u_0^{(k)} \neq 0$ unless stated otherwise. We consider two partitioning methods, based on the spatial critical paths defined by $u_x(x,s)=0$, respectively $g_x(x,s)=0$.

(i) $u_x(x,s)=0$:

- $u_0^{(1)}=0$ corresponds to a regular critical path.
- $u_0^{(1)}=u_0^{(2)}=0$ indicates an annihilation event. In Thom's "List of the Seven Elementary Catastrophes" this represents a fold catastrophy, with control parameter s.
- Inflection paths defined by $u_{xx}(x,s)=0$ provide separatrices in (x,s)-space, separating peaks, dales, and void regions. They connect in a similar annihilation event.

(ii) $g_x(x,s)=0$:

Type I: $u_x(x,s)=0$:

- $u_0^{(1)}=0$ corresponds to a regular critical path.
- $u_0^{(1)}=u_0^{(2)}=0$ corresponds to a "pitchfork": 3 regular critical paths for $s<0$ meet at the origin, leaving 1 for $s>0$. In Thom's list this represents a fold catastrophy, with 1 control parameter, viz. s.

Type II: $u_{xx}(x,s)=0$:

- $u_0^{(2)}=0$ corresponds to a regular critical path.
- $u_0^{(2)}=u_0^{(3)}=0$ indicates an annihilation event. (No critical points of u are involved.) In Thom's list this represents a cusp catastrophy with 2 control parameters, s and $u_0^{(1)}$.

Upon increasing scale all regions, including void, will merge into an encompassing region. Under mild conditions there exists a scale $S>0$ such that there is only one extremum for $s>S$, viz. a maximum. In this way we obtain a coarse-to-fine partitioning of the signal.

(The Netherlands Organisation for Scientific Research (NWO) is gratefully acknowledged for financial support.)

Multi-scale singularity trees. **Jon Sporring** (Københavns Universitet, Denmark) IC/MT2525/013

We propose and experimentally evaluate a novel scale-space image hierarchies called Multi-Scale Singularity Trees (MSSTs). For an n dimensional image, the spatial critical points ar extended to 1-dimensional manifolds (curves) in the $n+1$ dimensional space space - the image and its Gaussian blurred versions at all scales. These curves contain catastrophe points, where spatial saddle and extrema parts are joined.

MSSTs are constructed by connecting annihilating catastrophe

points based on the nesting of image segments in the scale-space. Because of the only generic catastrophes are the pairwise interactions between critical points in scale-space and two catastrophes never occur at the same scale, MSSTs are always rooted ordered binary tree.

MSSTs are powerful and unique because of their simple binary structure and straightforward construction method, and most importantly, their soft-linked nature, where all connections in MSSTs are accompanied by their strengths. Using the matching algorithm developed specifically for MSSTs to fully exploit their unique properties, the usefulness and performance of MSSTs are further shown experimentally.

Cahn–Hilliard inpainting and the Willmore functional. **Carola-Bibiane Schönlieb** (Universität Wien, Austria), Martin Burger (Universität Münster, Germany) IC/MT1234/013

The Cahn-Hilliard equation has its origin in material sciences and serves as a model for phase separation and phase coarsening in binary alloys. A new approach in the class of fourth order inpainting algorithms is inpainting of binary images using the Cahn-Hilliard equation proposed in [1]. Like solutions of the Cahn-Hilliard equation converging to two main values during the phase separation process, the grayvalues inside the missing part of the image are oriented towards the binary states black and white. My talk in this minisymposium is devided in two main parts. First I will present stability/instability results for solutions of the Cahn-Hilliard equation and their connection to the Willmore functional, mainly presented in [2]. In particular we will consider the Willmore functional as a quantity to find the optimal scale of the inpainting result. Further I will give some analytic results for the modified Cahn-Hilliard equation. In a subsequent work of [1] the authors present a first analysis including also existence and regularity results. We will extend these considerations with results for the stationary state and a special discretization.

Scale-space salient points. **Marco Loog** (Københavns Universitet, Denmark) IC/MT1983/013

We investigate statistical approaches to detect salient points in images; i.e., those locations that stand out conspicuously. The first one takes on a discriminatory standpoint, while the second one investigates the problem based on information theoretical considerations. Generally, both these approaches rely, either explicitly or implicitly, on a Bayesian rationale.

- In the discriminatory setting, classification tools from statistical pattern recognition and machine learning are employed. The basic underlying theory is that salient points are those that are easily discernable in the image; that is, they are readily discriminated from their surroundings. As we will show, discernibility can be quantified in terms of a supervised classification task and, consequently, it provides the statistical means to quantify this notion. As a result of this, learning tools can be utilized in the search for interest points.
- A different way of quantifying saliency is by means of the amount of information that a point adds to its surroundings. Informative points represent something of interest in an image scene and they can therefore be considered the salient points sought after. In this approach, the relative entropy, or the Kullback-Leibler divergence, will be the measure of prime interest that will be employed to provide a statistical information-driven quantity that describes the degree of saliency.

The fact that [physical] measurements should take place by means of apertures of finite size, also has its effect on how the salient point detection is actually carried out. In principle, point estimations cannot be performed and the information needed in both of the foregoing methods, typically has to come from neighborhood operators as provided by a Gaussian scale space framework. Consequences regarding information representation and saliency detection will also be discussed.

MR image reconstruction using the iterative-refinement method and nonlinear inverse scale-space methods. **Lin He** (RICAM Linz, Austria) IC/MT5016/013

Magnetic resonance imaging (MRI) reconstruction from sparsely sampled data has been a difficult problem in medical imaging field. We approach this problem by formulating a cost functional that includes a constraint term that is imposed by the raw measurement data in k-space and the L1 norm of a sparse representation of the reconstructed image. The sparse representation is usually realized by total variational regularization and/or wavelet transform. We have applied the Bregman iteration to minimize this functional to recover finer scales in our recent work. Here we propose nonlinear inverse scale space methods in addition to the iterative refinement procedure. Numerical results from the two methods are presented and it shows that the nonlinear inverse scale space method is a more efficient algorithm than the iterated refinement method.

Contour enhancement and completion via left-invariant second-order stochastic evolution equations on the 2D Euclidean-motion group. **Remco Duits** (Technische Universiteit Eindhoven, The Netherlands) IC/MT2518/013

Given an image $f : \mathbb{R}^2 \to \mathbb{R}$ we construct a local orientation score $U_f : SE(2) \to \mathbb{C}$, which is a complex-valued function of the Euclidean motion group $SE(2)$. The transformation $f \mapsto U_f$ is a wavelet transform constructed by an oriented wavelet $\psi : \mathbb{R}^2 \to \mathbb{C}$ and a representation $\mathcal{U} : SE(2) \to \mathcal{B}(\mathbb{L}_2(\mathbb{R}^2))$ of $SE(2)$, which boils down to convolutions with the oriented wavelet rotated at multiple angles. Under conditions on ψ the wavelet transform is unitary, inducing well-posed image reconstruction by the adjoint. This allows us to relate operators on images to operators on orientation scores in a robust way. To obtain Euclidean invariant image processing the operator on the orientation score must be left invariant. Therefore we consider left-invariant scale spaces on the Euclidean motion group $SE(2)$ generated by a quadratic form on left invariant vector fields of $SE(2)$. These scale spaces correspond to well-known stochastic processes on $SE(2)$ for contour completion and contour enhancement. The linear scale spaces on $SE(2)$ are given by group convolution with the corresponding Green's functions which were hitherto unknown. We derive the *exact* Green's functions and suitable approximations on a Group of

Heisenberg type, which we use together with the framework of invertible orientation scores for automatic contour enhancement and completion. We also consider *non-linear, adaptive* scale spaces on $SE(2)$ and their practical value in coherent enhancing diffusion.

Coordinate-free diffusion over compact Lie-groups. **Yaniv Gur** (Tel Aviv University, Israel), Nir Sochen (Tel Aviv University, Israel) IC/MT1421/013

We have seen in recent years a need for regularization of complicated feature spaces: Vector fields, orientation fields, color perceptual spaces, the structure tensor and Diffusion Weighted Images (DWI) are few examples. In most cases we represent the feature space as a manifold. In the proposed formalism, the image is described as a section of a fibre bundle where the image manifold is the base space and the feature space is the fibre. In some distinguished cases the feature space has algebraic structure as well. In the proposed framework we treat fibres which are compact Lie-group manifolds (e.g., $O(N)$, $SU(N)$, $Sp(N)$). We study here this case and show that the algebraic structure can help in defining a sensible regularization scheme. We solve the parameterization problem of compact manifold that is responsible for singularities anytime that one wishes to describe in one coordinate system a compact manifold. The proposed solution defines a coordinate-free diffusion process accompanied by an appropriate numerical scheme. We demonstrate this framework in few examples of S^1 feature space regularization which is known also as orientation diffusion.

IC/MP627/013: Novel matrix methods for internet-data mining.

Organiser: Lek-Heng Lim (Stanford University, USA)
Co-organiser: Anirban Dasgupta (Yahoo! Research, USA)
Co-organiser: Gene Golub (Stanford University, USA)
Co-organiser: Michael Mahoney (Yahoo Research, USA)

Classical matrix factorization techniques such as the LU, QR, EVD and SVD, or their variants, have been used with great success in various data analytic applications. These include information retrieval, text mining, bioinformatics, computer graphics, computer vision, product recommendations, etc. In the past few years, internet applications have thrown some new challenges to the numerical linear algebraists. Unprecedented features and problems inherent in internet data have rendered traditional matrix factorization techniques less effective. Some of the new issues that arise in internet data mining include:

(i) *prohibitively large data size*: internet data sets are often much too large to allow multiple random accesses;
(ii) *massively incomplete data*: a significant proportion of the data may be missing;
(iii) *novel structures in data*: most importantly, datasets whose underlying structure cannot be adequately unraveled by LU, QR, EVD or SVD have become increasingly common, not just in internet applications but also in other scientific and engineering fields.

In the last few years, several new matrix factorizations have been proposed to deal with these issues. Some notables ones include: 1. Nonnegative Matrix Factorization (NMF); 2. Maximum Margin Matrix Factorization (MMMF); 3. Matrix Subspace Factorization (CUR); 4. Sparse Overcomplete Decoding (SOD). The key difference between these and the classical matrix factorizations is that they are not *rank-revealing* in the traditional sense but instead they *reveal* other properties of the structure under consideration. This minisymposium will focus on the development of these and other novel matrix computational tools with a view towards internet data mining applications.

Random sampling in large matrices. **Ravi Kannan** (Yale University, USA) IC/MT3985/013

Best low rank approximations of matrices are found by Singular Value Decomposition. For very large matrices, good low rank approximations can be found much faster and with less Random Access storage using the recently developed CUR decomposition. Here C is a (small) random subset of columns of the given matrix A, R is a (small) random subset of rows and U is found from C,R. Under a judicious choice of sampling probabilities, it can be shown that CUR aproximates any given A well. Besides, it is interpolative (in that C,R are sub-matrices of A) and this is useful in scientific applications. The talk will also describe some more recent work on improving the CUR approximation to acheive small relative error with respect to the best approximation. Extensions to tensors and combinatorial applications will be described as well. The talk is partly a survey about the work of many people.

New fast algorithms for non-negative matrix factorization. **Ming Gu** (UC Berkeley, USA) IC/MT4928/013

We present new fast algorithms for computing the nonnegative matrix factorizations. Our algorithms are based on interior point methods for solving linear programs. We show a special matrix structure in the Schur complement matrix associated with the interior point methods. We further develep an efficient algorithm based on exploiting such matrix structures.

This is joint work with Gene Golub and Lek-Heng Lim.

Combinatorial Laplacian and rank aggregation. **Yuan Yao** (Stanford University, USA), Lek-Heng Lim (Stanford University, USA) IC/MT5022/013

A graph is a 1-dimensional simplicial complex and the graph Laplacian is its corresponding 0-dimensional *combinatorial Laplacian*. Graphs and graph Laplacians have well-known and important applications in computer science in general and in machine learning in particular. While higher-dimensional simplicial complexes and combinatorial Laplacians have often played important roles in discrete and computational geometry, they remain relatively unknown and unused in machine learning. In this paper, we will attempt to convince the reader that machine learning theorists and practitioners should also be interested in the higher-dimensional combinatorial Laplacian, and in particular, the 1-dimensional combinatorial Laplacians (on 1- or 2-dimensional simplicial complexes). These arises naturally when one studies the rankings of objects by different people. In this context, the 1-Laplacian is a surprisingly effective tool—among other features, it allows one to aggregate distinct rankings, resolve inconsistencies, deal with incompletely rankings, and incorporate cardinal information. The main result that we employ is a discrete version of the Hodge Decomposition Theorem. In graph theory or linear algebra, this is simply an orthogonal decomposition of weighted directed graphs or skew-symmetric matrices. In physics, this is the decomposition of an electric field into curl free, divergence free, and harmonic parts. When suitably applied to the problem of rank aggregation, we obtain an orthogonal decomposition of ranking data into a *consistent* component and an *inconsistent* component—with a further decomposition of the consistent component into a *global* (consistent acyclic) component and a *harmonic* (consistent cyclic) component. These are then used to deduce useful information from the ranking data.

Page-rank by basis pursuit. **Michael Saunders** (Stanford University, USA), Sou-Cheng Choi (Stanford University, USA) IC/MT4008/013

The PageRank eigenvector is sparse in the sense that most elements are extremely small. Basis Pursuit is a reasonable tool for finding the tiny proportion of significant non-zeros.

IC/MP627/013: Novel matrix methods for internet-data mining. #2

Co-organiser: Michael Mahoney (Yahoo Research, USA)

(For abstract, see session #1 above.)

An empirical meta-analysis for combining dependent hypothesis tests. **Art Owen** (Stanford University, USA) IC/MT3887/013

This work looks at combining several dependent statistical tests on related hypotheses. The motivating problem is a microarray experiment with $40 \times 16 \times 8932$ numbers. The goal is to identify which of 8932 genes are consistently related to aging in a subset of 16 tissues based on data from 40 individuals. The 16 test statistics for each gene are correlated. But patterns among the 8932 16-tuples may be used to estimate this correlation structure.

The Internet data mining connection is as follows: Similar problems arise in ecommerce and other fraud detection settings. There each entity suspected of fraud may be tested in multiple ways with the greatest suspicion falling on those that trigger multiple tests. Once again one has to combine dependent tests.

This work explains in detail some data analysis methods to be reported in a paper by Zahn *et al.* done in the Kim lab at Stanford University.

Maximum-margin matrix factorization. **Nathan Srebro** (Toyota Tech. Inst. at Chicago, USA) IC/MT3946/013

Factor, or linear component (PCA), models are often natural in the analysis of many kinds of tabulated data (e.g., collections of documents or images, gene expression measurements and user preferences). The premise of such models is that important aspects of the data can be captured by a small number dimensions (*component*,*factor* or *topics*).

I will present recent work on a novel approach that allows an unbounded (infinite) number of factors. This is achieved by limiting the norm of the factorization instead of its dimensionality. The approach is inspired by, and has strong connections to, large-margin linear discrimination. Unlike learning a low-rank factorization, learning a max-margin matrix factorization is a convex optimization problem that can be expressed as a semi-definite program, and I will discuss recent work on efficiently solving the resulting program, even on inputs with millions of observations. I will also discuss max-margin (low norm) factorizations and traditional low-rank factorizations as different measures of matrix complexity, and investigate the relationships between them.

I will use collaborative prediction (predicting unobserved entries of a partially observed matrix of user preferences) as an example application, and show how max-margin matrix factorizations are superior to previously suggested factorization methods for this task, and can achieve state-of-the-art prediction performance.

This is joint work with Alexandre d'Aspremont, Tommi Jaakkola, Jason Rennie, Adi Shraibman, Noga Alon and Sam Roweis.

Sampling-based algorithms for general regression problems. **Petros Drineas** (Rensselaer Polytechnic Institute, USA) IC/MT3956/013

ℓ_p regression algorithms have found numerous applications in many scientific domains. In this talk, we will argue that in the overconstrained case (i.e., given d variables and n constraints with n much larger than d), one can sample a small number of constraints and solve the induced problem in order to get relative error approximations to the original problem. The number of constraints to be sampled is a function of d and p. Particular emphasis will be placed on ℓ_1 and ℓ_2 regression problems.

Semi-nonnegative matrix factorization (NMF) and data clustering. **Chris Ding** (Lawrence Berkeley National Laboratory, USA) IC/MT3967/013

We show that the objective of NMF $X = FG'$ is equivalent to K-means clustering: G is cluster indicator and F contains cluster centroids. This can be generalized to semi-NMF where X, F contain mixed-sign data, with G being non-negative. We further propose convex-NMF by restricting $F$to be convex combinations of data points, ensuring F to be meaningful cluster centroids. We also show that the symmetric NMF $W = HH'$ is equivalent to Kernel K-means clustering and the Laplacian-based spectral clustering. All these follow by rewriting K-means objective as a trace of quadratic function whose continuous relaxation solution are given by PCA components. We emphasize orthogonality and nonnegativity in matrix based clustering. We derive the updating algorithms for semi-NMF, convex-NMF, symmetric-NMF and prove their convergence. We present experiments on face images, newgroups, web log and text data to show the effectiveness of these NMF based clustering.

Based on joint work with Xiaofeng He, Horst Simon, Tao Li and Michael Jordan.

IC/MP144/013: Laplacian eigenfunctions and their applications.

Organiser: Naoki Saito (UC Davis, USA)
Co-organiser: Mauro Maggioni (Duke University, USA)

Laplacian eigenfunctions have been successfully used in a variety of fields, such as image analysis, machine learning, data mining, computer graphics, and approximation theory. They are flexible to deal with high dimensional data with a lower-dimensional stochastic geometric structure. Moreover, together with the corresponding eigenvalues, they carry important geometric information about the domain where the data are sampled. The importance of the Laplacian eigenfunctions can be easily recognized by noticing that complex exponentials (or sines or cosines depending on the boundary conditions), spherical harmonics, and Bessel functions are in fact Laplacian eigenfunctions for specific canonical domains.

In this minisymposium, we shall showcase a variety of important and interesting applications employing Laplacian eigenfunctions and promote closer interactions among different communities listed above.

Laplacian eigenfunctions in geometry processing. **Bruno Levy** (INRIA Lorraine, France) IC/MT2916/013

The Laplacian operator plays an important role in Geometry Processing, as explained in the series of articles by Gabriel Taubin published at the Siggraph conference in the 90's. In this talk, we review the role of the eigenfunctions of this operator, by establishing the connections between existing works in various disciplines, comprising graph layout, dimension reduction, mesh parameterization, and more recent works on mesh quadrangulation. The talk is based on an article that we presented in the IEEE Shape Modeling International conference in 2006.

Can one hear shape?. **Martin Reuter** (Massachusetts Institute of Technology, USA) IC/MT850/013

The question "Can one hear the shape of a drum" has been asked in several contexts before (e.g., by Bers and Kac). It is a pictorial way of asking if the eigenvalues of the Laplacian on a given domain completely characterize its shape, in other words, if the spectrum is a complete shape descriptor (which it is not in general).

In this talk we will give an overview on how the computation of the spectra can be accomplished using FEM for manifolds in 2D and 3D (e.g. iso-surfaces, boundary representations, solid bodies, vector fields...) with the Dirichlet and Neumann boundary condition. We demonstrate that it is computational feasible to numerically extract geometric properties (volume, area, boundary length and even the Euler characteristic) from the first eigenvalues. Since the spectrum contains geometrical information and since it is an isometry invariant and therefore independent of the object's representation, parametrization, spatial position, and optionally of its size, it is optimally suited to be used as a fingerprint (Shape-DNA) in contemporary computer graphics applications like database retrieval, quality assessment, and shape matching in fields like CAD, medicine or engineering.

Laplacian eigen-maps as a tool for data analysis. **Mikhail Belkin** (Ohio State University, USA) IC/MT1346/013

I will discuss the importance of understanding geometry in various problems of data analyisis. Specifically, I will talk about the role of the Laplace-Beltrami operator as a key object associated to a Riemannian manifold, its usefulness for various tasks of data analysis and inference, and the problem of reconstructing the Laplace-Beltrami operator from sampled data.

Diffusion analysis of and on graphs, and high-dimensional data. **Mauro Maggioni** (Duke University, USA) IC/MT1143/013

We discuss ideas and constructions for the organization of graphs and data sets, based on random walks and diffusion processes on sets. One can generalize of Fourier and wavelet analysis to graphs and manifolds, leading to an organization of complex data sets and a generalization of signal processing tools to graphs. In order to emphasize the wide applicability of these techniques we will touch upon their applications to the organization of document corpora, dimensionality reduction for dynamical systems, nonlinear image denoising, semi-supervised and reinforcement learning.

IC/MP144/013: Laplacian eigenfunctions and their applications. #2

Organiser: Naoki Saito (UC Davis, USA)

(For abstract, see session #1 above.)

Laplacian eigenfunctions and physics Nobel prizes. **Lloyd Trefethen** (University of Oxford, UK) IC/MT2665/013

In recent years Timo Betcke and I have developed methods for high-accuracy computation of Laplacian eigenfunctions, building upon the method of particular solutions developed in the 1960s by Fox, Henrici and Moler here at the ETH. This talk will present some beautiful images resulting from these computations. It is remarkable how many physical phenomena can be seen in such results, and in particular, we shall relate Laplacian eigenfunctions to the Nobel Prizes in Physics awarded in 1902, 1903, 1907, 1909, 1918, 1919, 1933, 1952, 1963, 1964, 1977, and 1981.

Quantum mushrooms, scars, and the high-frequency limit of chaotic eigenfunctions. **Alex Barnett** (Dartmouth College, USA), Timo Betcke (University of Manchester, UK) IC/MT2422/013

It is a long-standing question how eigenfunctions of the Laplacian in a cavity behave asymptotically at large eigenvalue, when the ray or 'billiard ball' dynamics (Hamiltonian motion of a point particle in the cavity) is chaotic. This field is called 'quantum ergodicity' or 'quantum chaos', and has applications to physics, chemistry, acoustics, and connections to number theory and automorphic forms. It is known that almost every eigenfunction tends to spatial uniformity, however the *rate* at which this occurs is unknown. I investigate these numerically, at mode numbers up to of order 10^6, using specialized global approximation methods. I find evidence for the Quantum Unique Ergodicity conjecture of Rudnick-Sarnak, and for an ergodicity rate conjecture of Feingold-Peres involving the classical autocorrelation. I will also discuss the debate over 'scarring' (ghosts of periodic ray orbits in the eigenfunctions), and present work with T. Betcke on cavities such as Bunimovich's mushroom which possess both chaotic and integrable motion.

Laplacian eigenfunctions: fast computation via commuting integral operators and applications to image analysis. **Naoki Saito** (UC Davis, USA) IC/MT2579/013

Laplacian eigenfunctions, as a generalization of the Fourier basis over a rectangular domain, allow us to perform spectral analysis of data recorded on a domain of general shape. Examples include cells in histological images and meteorological data sampled at weather stations. We will present a method to analyze such images by expanding them in terms of the Laplacian eigenfunctions defined over such general shape domains. Directly solving the associated Helmholtz equations on such domains or computing the Green's functions satisfying specific boundary conditions imposed on such domains are in general difficult. Instead, we find an integral operator commuting with the Laplacian without imposing strict boundary conditions *a priori*, and compute the eigenfunctions of this integral operator, which are in fact the Laplacian eigenfunctions. This approach is amenable to modern fast numerical algorithms. In particular, we will discuss two possible strategies. One is to use multiwavelets of Alpert to sparsify the kernel of this integral operator to speed up the computation. The other is to use

the Fast Multipole Method as a fast matrix-vector multiplication, which is indispensable for large scale iterative eigenvalue-eigenvector solvers such as the Lanczos iteration.
In addition, we will present applications of Laplacian eigenfunctions to statistical image analysis and contrast them with Principal Component Analysis.

Random computational tomography and protein structuring. **Amit Singer** (Yale University, USA) IC/MT4809/013

In this talk we present a reconstruction algorithm for the 3D atomic structure of randomly oriented proteins using modified graph laplacians. The 2003 Nobel Prize in Chemistry was co-awarded to R. MacKinnon who was the first to structure a protein channel (the potassium channel) in 1998 by crystallizing the protein and using the classical X-ray computed tomography (CT). However, most membrane proteins cannot be crystallized and the classical CT cannot be used. In our experimental setup, the data consists of thousands of real noisy 2D projections (electron microscope images) of the protein given in random unknown directions, because the proteins are randomly oriented rather than being aligned as in MacKinnon's setup. Still, we show that the reconstruction is made possible by a certain modification of the images' graph laplacian coupled with the 3D Fourier slice theorem. The reconstruction is a particular case of a more general spectral non-linear independent component analysis (ICA) algorithm that combines local principal component analysis (PCA) with the graph laplacian. No prior knowledge of graph laplacians, tomography and proteins is needed for this talk. This is a joint work with Ronald Coifman, Yoel Shkolnisky and Fred Sigworth (Yale University).

IC/MP298/014: The AIM@SHAPE digital shape workbench as an e-Science collaboration tool.

Organiser: Ewald Quak (Tallinn University of Technology, Estonia)

Developing and maintaining computational research software has become a more and more complex endeavour, especially when considering aspects like quality control, training of young researchers, exchange between different teams and also to avoid reinventing the wheel.
The EU IST Network of Excellence AIM@SHAPE (www.aimatshape.net) on 3D shape modelling involves ca. 200 researchers and graduate students, coming from 13 institutions in 8 countries. Application areas in the project include industrial design, the link between geometrical representations and numerical simulation software as well as the use of virtual humans.
One of the most important project goals is to develop a Digital Shape Workbench (DSW) as an international software infrastructure for research in 3D shape modelling using suitable ontologies. As a collaboration tool the DSW is meant to be freely accessible for researchers in the subject area, well beyond the consortium that is currently building it.

This minisymposium is one of the means to popularize the Digital Shape Workbench in the scientific community of potential users. Apart from a general introduction to the research infrastructure provided by the network, the use of the shape model and software tools repositories will be demonstrated. Also some examples for the role of the DSW in the research program of the network will be presented.

The AIM@SHAPE DSW: semantic-centric usage scenarios. **Manolis Vavalis** (ITI-CERTH, Greece) IC/MT1526/014

In this paper we present case studies where semantic technologies have the potential to be used to build robust real-life solutions out of the AIM@SHAPE Digital Shape Workbench both in its current and its future forms. The aim of this study is not to actually report on the success (or failure) of existing usage scenarios but to focus on understanding what makes semantic knowledge applications successful in operational environments which involve shapes.

Mathematical aspects involved in virtual human construction and simulation for industry. **Laurent Moccozet** (Université de Genève, Switzerland), Frederic Vexo (École Polytechnique Fédérale de Lausanne, Switzerland) IC/MT1871/014

Virtual Humans are more and more involved in Virtual Environments for various areas of applications in industry: ergonomics, training, video games ... For all these applications, sophisticated models that reproduce as closely as possible not only the shapes of real Humans but also their dynamic behavior and their interactions with the environment are required. Thanks to the combination of currently available shape and motion acquisition devices with geometrical shape analysis and processing tools, it becomes possible to define accurate virtual models with limited efforts.

Combining modeling, simulation, optimization and analysis under a unique framework. **Sebastian Pena Serna** (Fraunhofer-IGD, Germany), Andre Stork (Fraunhofer-IGD, Germany) IC/MT2460/014

The virtual engineering process has several phases and every phase needs special representations and/or tools. The process itself is complex and in addition, one has to deal with conversions, transformations and transitions between phases which consume time and therefore increase the complexity, the incompatibility and the expenses. On the other hand, the phase teams are not integrated because of this incompatibility and hence, new and advanced concepts, methodologies, approaches and applications cannot be defined in order to solve and support their needs and requests.

Hence, we are defining, designing and developing a framework where the phases of the virtual engineering process can be executed, integrated and combined without transitions or conversions. In order to achieve our target, we have chosen the mesh representation as the unique representation, because this is the most typical representation for 3D domains within the engineering analysis. Additionally, we are enriching the mesh with mathematical definitions which should allow for combining modeling, simulation, optimization and analysis under the same framework and therefore simplifying the virtual engineering process. This approach will support the engineers with advanced techniques on modeling meshes, conceptual simulations, real time optimization and more accurate analysis.

Contributions to robust scattered data denoising. **Oliver Schall** (Max-Planck-Institut Informatik, Germany) IC/MT1703/014

Many of today's applications make use of 3D data digitized from real-world objects such as machine parts, terrain data, and cultural heritage. In spite of recent progress in developing reliable methods for denoising scattered data, the quest for accurate, and adaptive denoising techniques capable of processing large and very noisy datasets remains a major research issue in computer graphics and geometric modeling.

In this talk, an overview of recent developments in scattered

data filtering will be given. Special attention will be paid to new denoising techniques developed within the AIM@SHAPE framework. In particular, contributions related to processing uncertain and time-varying data will be discussed.

IC/MP298/014: The AIM@SHAPE digital shape workbench as an e-Science collaboration tool. #2

Organiser: Ewald Quak (Tallinn University of Technology, Estonia)

(For abstract, see session #1 above.)

The AIM@SHAPE network of excellence and its research infrastructure for shape modelling. **Bianca Falcidieno** (Consiglio Nazionale delle Ricerche, Italy), Ewald Quak (Tallinn University of Technology, Estonia) IC/MT1533/014

This is the scene-setting introductory talk of this minisymposium. The scope of the AIM@SHAPE network is described and the network's general goal is addressed: to use techniques from knowledge technology, such as ontologies, in shape modelling research. An overview is given on the main tangible outcome of the project, namely the features of a lasting research infrastructure, accessible to the research community as a whole. The core element is formed by the AIM@SHAPE Digital Shape Workbench (DSW), where the necessary flow of interaction and communication is implemented that allows to access and to use the various software components developed and maintained by the project. The detailed use of the DSW and specific research results from the network are then described in the following lectures.

The AIM@SHAPE shape repository. **Waqar Saleem** (Max Planck Institut Informatik, Germany) IC/MT1935/014

In a space of a little over 2 years, the AIM@SHAPE Shape Repository has become one of the European reference databases for digital shape models. The repository is populated by AIM@SHAPE project partners with digital shape models that either reflect their ongoing research or are acquired exclusively for the repository. The repository itself is ontology-driven, i.e. stored models are categorized using the AIM@SHAPE Shape Common Ontology. The shape category then determines the necessary metadata that will accompany the model.

In my talk, I will present some background on the Shape Repository followed by a demo. I will first demonstrate how the Shape Repository meets all expectations a user may have from a standard online digital shape database, and then go on to its unique features. Finally, I will talk about how online users can help to improve it.

The AIM@SHAPE tool repository. **Laurent Saboret** (INRIA Rocquencourt, France), Pierre Alliez (INRIA Sophia Antipolis, France) IC/MT1519/014

The tool repository of the AIM@SHAPE Network of Excellence is an inventory of shared software that collects and documents a number of state-of-the-art tools that can be used at different stages of the digital shape lifecycle. In this talk we will present some of the tools at work in two scenarios. In the first scenario a physical shape is acquired using a laser scanner, processed, structured and semantically annotated. The second goes the other way around, from the semantic to the final geometric realization of a shape.

Bridging geometry and semantics: the AIM@SHAPE research perspective. **Michela Spagnuolo** (Consiglio Nazionale delle Ricerche, Italy), Jean-Claude Leon (Institut National Polytechnique Grenoble, France), Fatih Demirci (Universiteit Utrecht, The Netherlands) IC/MT2042/014

The scientific innovation sought by AIM@SHAPE is to move towards digital representations of shapes which are able to model not only the visual appearance of objects but also their meaning or functionality in a given knowledge domain.

While the technological advances in terms of hardware and software have made available plenty of tools for using and interacting with the geometry of shapes, the interaction with the semantic content of digital shapes is still far from being satisfactory. While we have tools for viewing digital shapes even in much unspecialised web contexts (e.g. browsers plugins like SVG or VRML for 3D shapes), we miss tools for interacting with the semantics of digital shapes.

If we want to move towards semantically capable digital representations of shapes, we have to put an entirely new perspective on the traditional modelling pipeline, trying to understand where and how the semantics can be encapsulated in the digital representation of shapes.

With this background, results and open issues will be presented mainly focused on the different stages at which it is necessary to formalize an interaction between the semantic and the geometric level of representation of 3D shapes, both in top-down and bottom-up pipelines of modelling.

IC/MP4421/014: Level-set methods: current development.

Organiser: Yen-Hsi Tsai (University of Texas at Austin, USA)

Several problems that arise in science and engineering can be formulated as a front evolution between two (or more) phases. Examples include solidification problems, dendritic growth in materials science, free surface flows, multiphase flows, to cite a few. One of the main the difficulties in solving such problems comes from the fact that the interface location must be computed as part of the solution to the underlying equations. Since their inception, level set methods have been extremely successful in tackling these problems. In this minisymposium, the focus will be given In this minisymposium the focus will be given to recent advances in the core level set algorithms as well as their applications. Specifically, the core algorithm will cover topics on adaptivity, volume conservation, and solving inverse problems. Applications will include multiphase flows, high frequency wave propagation and shape optimization. This minisymposium will offer an excellent opportunity for researchers to learn about a wide variety of recent developments in the computational aspects of level set methods as well as their applications and will stimulate cross-pollination between disciplines.

Computational high-frequency waves through barriers or interfaces. **Shi Jin** (University of Wisconsin, Madison, USA) IC/MT1344/015

We introduce Eulerian methods that are efficient in computing high-frequency waves through barriers or interfaces. The method is based on the classical Liouville equation in phase space, with discontinous Hamiltonians (or singular coefficients) due to the barriers or material interfaces. We provide physically relavant interface conditions consistent with the correct transmissions and reflections, and then build the interface conditions into the numerical fluxes. This method allows the

resolution of high frequency waves without numerically resolving the small wave lengths, and capture the correct transmissions and reflections at the interface. Moreover, we extend the method to include diffraction, and quantum barriers. Applications to semiclassical limit of linear Schrödinger equation, geometrical optics, elastic waves, and semiconductor device modeling, will be discussed.

Discrete δ-functions concentrated on level sets. **Peter Smereka** (University of Michigan, Ann Arbor, USA) IC/MT1173/015

It is shown that a discrete delta function can be constructed using a technique developed by Anita Mayo for the numerical solution of elliptic equations with discontinuous source terms. This delta function is concentrated on the zero level set of a continuous function. In two space dimensions this corresponds to a line and a surface in three space dimensions. Delta functions that are first and second order accurate are formulated in both two and three dimensions in terms of a level set function. The numerical implementation of these delta functions achieves the expected order of accuracy.

Discretizing δ functions supported on level-sets. **John Towers** (MiraCosta College, USA) IC/MT1350/025

I will explain how an effort to solve a certain parabolic free boundary problem related to flame propagation resulted in some new methods for computing delta functions supported on level sets. For the purpose of computing an integral over a manifold of codimension one defined by a level set, these methods yield approximations that are accurate, have relatively small bandwidth, and are known to be convergent. The one-dimensional version of one these algorithms also seems to be well suited to approximating the type of singular integral that arises when computing multivalued observables for the semiclassical limit of the Schrödinger equation (with one space dimension) using the level set method. In more than one spatial dimension, this problem requires the calculation of singular integrals of higher codimension, possibly requiring a different technique. I will report on progress toward extending this technique, and a new technique that exploits the full codimension aspect of the problem, to these singular integrals.

Geometry-aware discretizations of level-set methods: application to tumor growth. **John Lowengrub** (University of California, Irvine, USA) IC/MT3247/015

An advantage of using level set methods for moving boundary problems is that geometric quantities such as curvature can be readily calculated from the level set function. However, in topologically challenging cases (e.g., when two interfaces are in close contact), level set functions develop singularities that yield inaccuracies when using traditional discretizations. In this talk, we discuss improvements to the algorithms such that second order accuracy is achieved near transitions. We then develop a 2nd order accurate level-set/ghost-fluid algorithm for use with mathematical models of solid tumor growth. A novel feature of this algorithm is the accurate treatment of normal jumps across the interface.

A hybrid coupling interface method for elliptic complex interface problems. **Yu-Chen Shu** (National Taiwan University), I-Liang Chern (National Taiwan University) IC/MT3855/025

In dealing with elliptic *complex* interface problems, most finite-difference methods under Cartesian grid fail due to their restrictions to the interfaces for the purpose of interpolation. In this paper, we first propose a first-order coupling interface method (CIM1) in any dimensions which uses only the standard nearest neighboring grid data. It only requires that each grid segment (the segment connecting two adjacent grid points) intersects the interface at most once. As a result, it is robust and flexible to handle complex interface problems.

Next, we propose a hybrid coupling interface method (hybrid CIM) to get higher order accuracy for handling elliptic complex interface problems in arbitrary d dimensions. We classify the underlying Cartesian grid points into interiors, normal on-fronts and exceptionals. Standard central finite difference is used at interior grid points. A second-order coupling interface method (CIM2) proposed in our previous paper is adopted at those normal on-front points. The CIM1 is applied at the exceptional points. This hybrid coupling interface method maintains second order accuracy in most applications due to the fact that usually the number of normal on-front grid points is $O(h^{1-d})$ and the number of the exceptional points is $O(1)$.

We compare our hybrid CIM with other interface method that handle complex interface problems in two dimensions, our method is robust and produces less errors. In addition, we perform several numerical tests in three dimensions. The results show that the hybrid CIM can maintain second order accuracy for complex interface problems.

Conjugate-gradient and quasi-Newton methods for level-set-based shape-optimization problems. **Wolfgang Ring** (Universität Graz, Austria) IC/MT4252/015

The nonlinear conjugate-gradient method and the class of quasi-Newton methods are typical examples of optimization techniques which rely on the vector space structure of the set of optimization variable. For the CG-method, the descent direction is constructed as $p_{k+1} = -\nabla f_{k+1} + \beta_k p_k$ i.e. a linear combination of the gradient direction in the current point and the descent direction in the previous point. Similarly, quasi Newton method use finite differences of gradients in the current and the previous point for the construction of the approximate Hessian. When applying these ideas to the solution of shape optimization problem, one faces the difficulty that shapes are not elements of a vector space (at least not in a straight forward way), and hence the update formulas have to be modified. We suggest to use the level-set method for the transport of information between successive iterates produces by the optimization algorithm.

Inverse problems involving shapes. **ChiuYen Kao** (The Ohio State University, USA) IC/MT3386/015

Identification or optimization of shapes arises in many science and engineering applications. Recently shape derivatives and topological derivatives have been incorporated into level set method to study inverse problems involving shapes. This talk will provide an integrated introduction to the basic definition of shape derivatives and topological derivatives, and the combination with level set methods in a descent framework. Finally, specific applications for identifying shapes of drums and optimization of quality factor are presented.

Existence and uniqueness of level sets for spiral crystal growth. **Takeshi Ohtsuka** (Sophia University, Tokyo, Japan) IC/MT3957/015

The aim of this talk is to propose a new level-set approach for spirals.

In 2003, I adjusted the level-set formulation for the spiral crystal growth, and prove the existence and uniqueness of viscosity solutions for a level set equation. The formulation reflects an idea of R. Kobayashi who introduced a kind of Allen–Cahn formulation for the spiral crystal growth. To complete the strategy to obtain spiral curves by this level set formulation, we see the uniqueness of level sets and construct an initial datum by initial curves.

To prove the uniqueness, we adjust the way to prove the uniqueness for the usual level set formulation due to Y.-G. Chen, Y. Giga, and S. Goto, and L.C. Evans and J. Spruck. Their strategy is to use the comparison principle and the rescaling invariance of solutions for geometric equations. However, the level set equation for spiral crystal growth is not geometric. To overcome this difficulty, we introduce a new rescaling of dependent variables which represents dislocation as a level set, and its invariance. I also show the way to construct an initial datum in several simple cases and the result of numerical computation.

Quasi-Newton algorithm for best multi-linear rank approximation of tensors. **Berkant Savas** (Linköpings universitet, Sweden) IC/CT4745/015

In this talk we introduce a novel method for solving the best multilinear rank approximation problem. Our algorithm differs from existing methods in two respects: (1) it exploits the fact that the problem may be viewed as an optimization problem over a product of Grassmann manifolds; (2) it uses Quasi-Newton-like Hessian-approximates specially adapted for Grassmannians and thus avoids the inevitable problem of large Hessians in such problems. Tensor approximation problems occur in various applications involving multidimensional data. The performance of the Quasi-Newton algorithm is compared with the Newton-Grassmann and Higher Order Orthogonal Iteration algorithms for general and symmetric 3–tensors.

Methods and a system of functional programming for supporting supercomputing. **Victor Kasyanov** (Institute of Informatics Systems, Russian Federation) IC/CT472/015

In the paper the SFP project being under development at the Institute of Informatics Systems in Novosibirsk is considered.

The SFP system is intended to be a visual interactive programming environment that simplifies construction of correct parallel programs by isolating the programmer from the complexities of parallel processing and supports development of high quality, portable software for parallel computers on low cost, sequential computers (PC).

The SISAL 3.0 language that has been designed as the input language of SFP supports annotated functional programming, exposes implicit parallelism through data dependence and guarantees determinate result.

The SFP system uses intermediate languages of hierarchical graphs and provides means to write and debug SISAL-programs regardless target architectures as well as to translate the SISAL-programs into optimized imperative programs, appropriate to the target execution platforms.

The author is thankful to all colleagues taking part in the SFP project. The work is partially supported by the Russian Foundation for Basic Research (under grant N 07-07-00056).

Soft-fuzzy computing and modelling. **Witold Kosiński** (Polish-Japanese Inst./Kazimierz Wielki University, Poland) IC/CT3099/015

In real-life problems both parameters and data used in mathematical modelling are *vague*. The vagueness can be described by fuzzy numbers and sets. Pattern recognition, system modelling, diagnosis, image analysis, fault detection and others are fields where soft calculation with unprecise, fuzzy objects plays an important role. In the paper a short review of recent results in the theory of ordered fuzzy numbers and their normed algebra is given.

Ordered fuzzy numbers are generalizations of *convex* fuzzy numbers that make possible to deal with fuzzy objects exactly in the same way as with real numbers. They form a Banach space, partial ordered ring and even more a *commutative Banach algebra* with unity. Linear and bounded functionals which form a large class of *defuzzyfication operators* are represented here by sums of two Stieltjes integrals with respect to functions of a bounded variation. An approximation formula of a general nonlinear defuzzyfication operator is also derived.

Specific applications in finance, dynamical systems and mechanics are presented. From the classical framework known algebraic and evolution equations describing such systems are transformed into their fuzzy versions. Their solvability is shortly presented together with the specially dedicated problem solutions.

Direct reconstruction of complex refractive-index distribution. **Akambadath Keerthiyil Nandakumaran** (Indian Institute of Science Bangalore) IC/CT4275/001

Diffraction tomographic reconstruction of refractive-index distribution requires complete knowledge of the transmitted complex field at the boundary. Here we present a method which can reconstruct the complex refractive index distributions from intensity-based measurements which are logarithm of intensity and the normal derivative of intensity. We have presented an iterative algorithm which requires efficient implementation of a forward wave propagation equation and sensitivity matrices for the above two type of measurements. An efficient method for estimation of the sensitivity matrices is given and also the forward operator. The results of numerical experiments show that the two data types, namely $log(I)$ and $\frac{\partial I}{\partial n}$ reconstruct respectively the imaginary and real part of the refractive index distribution. The forward operator, a Helmholtz equation, is implemented for small k(k=50 in our example). As a consequence, the reconstructed inhomo-

geneities are spread and smoothened. Implementation of the Helmholtz equation for large k requires very fine meshing which pushes up computation and numerical instability. For the present method to be applicable in optical refractive index reconstruction an accurate and efficient forward solver for large k is required. This is currently being attempted using a wavelet-based, multi-scale procedure.

A novel two-factor forecasting model for fuzzy time series. **Sheng-tun Li** (National Cheng Kung University, Taiwan), Su-Yu Lin (National Cheng Kung University, Taiwan), Yi-Chung Cheng (National Taiwan Normal University) IC/CT4271/013

Recently, the forecasting model of fuzzy time series has attracted a lot of interests since it is capable of dealing with vague and incomplete time series data represented as linguistic values under uncertain circumstances. In this paper, we propose a novel two-factor forecasting model for fuzzy time series. In contrast to related work, the proposed model can reduce the computation complexity without deriving all fuzzy logic relationships in advance. Moreover, it can overcome the hurdle of determining the k-order issue in other high order models. A fuzzy C-means clustering algorithm is utilized in fuzzifying and partitioning intervals for the historical data. Experimental results demonstrate that our model not only achieves the better accuracy with the mean square error and average forecasting error rate than previous models, but also is considered as robustness under a simple Monte Carlo simulation. The consistency performance about the number of intervals is coincided with the principle that the more the number of intervals is, the better the forecasting accuracy is achieved.

Fast 3D surface-mesh denoising with edge preservation and mesh regularization. **Hui Huang** (University of British Columbia, Canada), Uri Ascher (University of British Columbia, Canada) IC/CT4259/012

We describe a hybrid algorithm that is designed to smooth, but not only smooth, noisy polygonal surface meshes with sharp edges. While denoising, our method simultaneously regularizes triangle meshes on flat regions for more advanced processes and preserves edge sharpness for authentic visualization. A clustering technique, which combines K-means and spectral clustering methods, is first developed according to our specific geometry prior. It is then used to implement vertex classification so that we can subsequently apply different smoothing operators on different vertex groups. This yields a highly efficient robust algorithm that is capable of handling both edge sharpness and mesh sampling irregularity without any significant cost increase.

Towards a high-content analysis of high-throughput imaging data: multiparametric analysis of siRNA phenotypes and their reproducibility. **Yannis Kalaidzidis** (Max-Planck-Institut Dresden, Germany) IC/CT4691/000

One key challenge of the post-genomic era in biology is the elucidation of gene functions and the mechanistic understanding of cellular processes in which the genes participate. Gene silencing by means of siRNA/esiRNA knockdown in conjunction with high-throughput microscopy-based readouts offer a promising approach. However, the large degree of morphological variation between cells in an image frame represents a major challenge to the reliable identification of siRNA-phenotypes. At present, most high-throughput imaging experiments have therefore resorted to an almost qualitative readout. Is the cell infected? Is the cell cycle blocked?. Accessing the quantitative information in the image sets would be desirable both in reducing the number of false negatives as well as allowing more accurate classifying phenotypes. Using the sub-cellular distribution of endosomal organelles as assay, we have developed a system for the high-content analysis of automatically-acquired high-resolution images. More than 10 parameters describing the intra-cellular distribution of endosomal organelles in quantitative terms were developed. The stability of parameters was tested by calculation the correlation between different imaging sessions and between experimental replicates. The analysis showed that different parameters reveal a wide variation of stabilities which dependent on biological variability, typical automatic imaging problems and parameter calculation details. The comparison of parameters stability between different siRNAs targeting the same gene with respective stability between different replicates provides a tool for establishing the phenotype reproducibility by siRNA technology. Statistical analysis of these data will be of critical importance in establishing objective phenotype definitions and thus for the experimental design of the next generation of high-content screens.

Software engineering for numerical simulation of 2D non-stationary real MGD flows. **Livio Maglione** (Universidad Nacional de Río Cuarto, Argentina), Sergio Elaskar (Universidad Nacional de Córdoba, Argentina), Hector Brito (Universidad Nacional de Río Cuarto, Argentina), Raul Dean (Universidad Nacional de Río Cuarto, Argentina), Luis Lifschitz (Universidad Nacional de Río Cuarto, Argentina) IC/CT3381/010

The study of flows in which a electrically conducting gas moves in a magnetic field is known as magnetogasdynamics or MGD for short. Computational MGD represents one of the most promising interdisciplinary computational technologies for aerospace design. At the present, in Argentina, it is being developed an ablative magnetoplasmadynamic thruster (AMPD) as a native propulsion option for satellite and, particularly, microsatellite orbit and/or attitude control.

A MGD model is generally based on the assumption that plasma can be regarded as a continuum and thus may be characterized by relatively few macroscopic quantities. A model for a flow affected by electromagnetic forces includes the full set of Maxwell's equations coupled with the Navier–Stokes equations. The real MGD equations constitute a parabolic–hyperbolic partial differential system. In addition the ideal part of the MGD equations is nonconvex and as consequence the wave structure is more complicated than for the Euler equations.

A software engineering was developed and using structured meshes solves 2D, time-dependent, viscous and resistive MGD flows. In this case, the numerical approach consists of an approximate Riemann solver coupled with the TVD scheme proposed by Yee. The eigensystem introduced by Powell and the normalization of the eigenvectors presented by Zarachay *et al.* have also been used.

To check accuracy, the computational code has been applied in the simulation of a Riemann problem introduced by Brio and Wu. Also results in the simulation of the Hartmann flow are shown. The results obtained are in good agreement with those reported by other authors.

Adaptive numerical simulation of intracellular calcium dynamics. **Nagaiah Chamakuri** (Universität Magdeburg, Germany) IC/CT5065/012

In my talk I will present the adaptive numerical simulation of intracellular calcium dynamics. Calcium is an important second messenger in cell communication. The dynamics of intracellular calcium is determined by the liberation and uptake by cellular stores as well as reactions with buffers. We develop models and numerical tools to study the liberation of calcium from the endoplasmic reticulum (ER). This process is characterized by the existence of multiple length scales. The modelling of diffusion, binding and membrane transport of calcium ions in cells leads to a system of reaction-diffusion equations. We used piecewise linear finite elements for the spatial discretization and time discretization by a linearly implicit Runge–Kutta scheme. In our description the dynamics of IP3-controlled channels remains discrete and stochastic. The strongly localized temporal behaviour due to the on-off behaviour of channels as well as their spatial localization is treated by an adaptive numerical method. We present sequential and parallelized numerical results.

The 3D-asymptote generalization of the MetaPost Bézier interpolation algorithms. **John Bowman** (University of Alberta, Canada) IC/CT3271/013

The descriptive vector graphics language Asymptote provides for the typesetting of mathematical figures a capability analogous to what TEX provides for typesetting equations (http://asymptote.sourceforge.net/). It was inspired by Hobby's MetaPost (a modified version of MetaFont, the program that Knuth wrote to produce the TEX fonts) but features a more elegant C++-like syntax, high-order functions, and robust floating-point numerics. Labels are typeset with TEX, for professional quality and overall document consistency, and the simplex linear programming method is used to solve overall size constraint issues between fixed-sized and scalable objects.

Asymptote generalizes to three dimensions the prescription of Hobby (Discrete and Computational Geometry **1**, 1986) for drawing an aesthetically pleasing, numerically efficient, interpolating spline given a set of nodes and optional tangent directions. This generalization is shown to be shape-invariant under three-dimensional rotation, scaling, and translation, and reduces in the planar case to Hobby's prescription. Both the nodes and control points of the three-dimensional Bezier curves are projected to two-dimensional Bezier curves.

Asymptote was designed to generate native Postscript and PDF output since these are the portable standards understood by professional printers. However, Postscript and PDF support only Bezier splines, which are invariant under orthographic (affine) but not perspective projection. Since non-uniform rational B-splines, which are invariant under perspective projection, cannot be reduced to Bezier splines without loss, it is important to consider the error introduced by using three-dimensional cubic Bezier splines for perspective drawings.

Given that all Metapost and Asymptote guarantee is that the path passes through a set of nodes, respecting any explicit tangent and straightness conditions, we argue that, in practice, the error inherent in using Bezier splines for drawings with perspective distortion is as acceptable as the usual 0.06% accurate 4-node Bezier approximation to a circle. In both cases, one can always specify additional nodes and control points to obtain any desired graphical accuracy.

The reassignment method with the Stockwell transform. **Cheng Liu** (York University, Canada) IC/CT2551/013

Instantaneous frequency (IF) is a critical parameter in describing non-stationary signals whose frequency characteristics vary over time. In real application, it is usually difficult to obtain accurate IF estimation of signals in terms of their multi-component feature and the presence of noise. The reassignment method provides a technique to obtain a more concentrated IF representation by re-locating the original information of time-frequency representation. In this talk, we will extend the reassignment method with the recently developed time-frequency representation: the Stockwell transform. The improvement of our new methodology is shown by numerical simulations.

Constraint isomorphism and correction algorithms for violations. **Toshinori Munakata** (Cleveland State University, USA), Adam Fadlalla (Cleveland State University, USA) IC/CT1736/013

In many domains such as science, engineering and operations research, a problem is characterized in terms of different parameter sets. A constraint imposed in terms of a parameter in one parameter set must be consistent with a constraint in another parameter set. We call such consistency among parameter sets *constraint isomorphism* [1]. When mapping among the parameter sets is not so visibly obvious, one might overlook consistency violations, which have occurred in the past. Constraint isomorphism is important in many situations, including generation of random data for simulation of stochastic problems.

As a case study we consider the total tardiness problem, an NP-complete job scheduling problem. Two parameter sets are commonly employed for this problem. For easy reference, we call one set "data parameters" and the other "characteristic parameters." Processing time and due date for each individual job are data parameters, and the tardiness factor τ and relative range of due dates δ are characteristic parameters. For the simplest, single machine model, each job is processed by the single machine at a time. n jobs wait for processing at time t = 0, and they have *processing times* p_1, p_2, ..., p_n, and *due dates* d_1, d_2, ..., d_n, respectively. The objective of the problem is to determine the order of jobs to be processed to minimize the *total tardiness*. Extensive works have been performed for the tardiness problem, employing various methods. A common scenario is that each of the τ and δ values is selected from a set of numbers. It has been shown that some of these selected pairs yield two types of violations: 1. Non-negative due date. The due date for every job must be non-negative, that is, $d_i \geq 0$. 2. Due date $\geq$ processing time for every job, i.e., $d_i \geq p_i$.

We present several algorithms to remove these violations. They include: discard-and-replace, modified probability distributions, and data-interchanging. The upper bound of the computational complexity of the last algorithm is O(*mn* log (*mn*)), where m is the number of problems in the entire problem set under consideration.

Data-uncertainty analysis in environmental management. **Michal Hejc** (Masaryk University, Czech Republic), Jiri Hrebicek (Masaryk University, Czech Republic) IC/CT2857/013

Imprecision of data is an important characteristic feature of environmental monitoring, particularly at all kinds of fixed and moving sensor networks. When making evaluations, conclusions and the decisions from collected data, we have to assess data quality not to make fatal mistake. The important task of computing and current information management is to deal with the primary data uncertainty and using knowledge about data quality to assure the new architecture is generic enough and provides added value for the end users. This will reduce the risk of wrong decision in environmental management. At present new approaches and methodologies to handle environmental data uncertainty are explored as opposite to standard. The paper presents comparison of such new approach against European Environment Agency and U.S. Environmental Protection Agency standards in the several cases of the assessment of environmental management indicators in the Czech Republic. The new approach to information management with data quality assessment brings more flexible way of dealing with all kinds of uncertainty. There are presented better results and less workload then standard approach in the paper.

Markovian model of genetic algorithms and its asymptotic behaviour. **Witold Kosiński** (Polish-Japanese Inst./Kazimierz Wielki University, Poland), Stefan Kotowski (Polish Academy of Sciences, Poland) IC/CT3106/011

In the last time there has been growing interest in universal optimization algorithms, which use only limited knowledge about problems to be solved and are constructed on the basis of some similarity to processes realized in nature. Between them are *genetic algorithms* which perform a multi-directional search by maintaining a *population* of potential solutions and encourages information formation and its exchange. A population undergoes a simulated evolution due to the iterative action with some probability distributions of a composition of three operators: *mutation, crossover and selection*. If we imagine that a population is a point in the space Z of (encoded) potential solutions then the effect of one iteration of this composition is to move that population to another point.

In our analysis first we are concerned with probability distributions of each population for a particular case of the simple genetic algorithm (SGA) in which crossover is not present and then we admit for adaptation of algorithm parameters during the evolution. In SGA with known fitness function the *proportional selection* and the mutation allow to write the probability distribution for the next population in the form of the multiplication of two matrices times the population (frequency) vector. Finally the composition of both operations leads to the general form of the *transition operator* (matrix) acting on a new probability vector representing a probability distribution of appearance of all populations of the same *size*. The matrix appearing there turns to be Markovian and each subsequent application of SGA is the same as the subsequent composition of that matrix with itself. Thanks to the well-developed theory of Markov operators new conditions for the *asymptotic stability*: general and point-wise of the transition operator, are formulated. The case of different selection operators is also treated.

Computing, Posters

IC/PP3894/012: Application of the R-functions method to the solution of the Poisson equation.

Presenter: Svyatoslav Gladkov (Universität Dortmund, Germany)
Co-author: Bob Svendsen (Universität Dortmund, Germany)

Present-day solution techniques for partial differential equations (PDEs) in more than one dimensions require the use of various spatial discretization schemes like finite elements method (FEM) or boundary elements method (BEM). But for complicated geometric domains the problem of creating meshes (or simply – meshing) is still a tricky question. Various meshless and meshfree approaches were developed to avoid spatial discretization. One of these methods is the so called *R-functions method (RFM)* which discretizes the underlying functional space.

In 1963 Kantorovich observed that the solution of the problem

$$-\Delta u(\mathbf{x}) = f(\mathbf{x}) \ \text{ in } \Omega, \quad u(\mathbf{x}) = 0 \ \text{ on } \partial\Omega,$$

where $\Omega \subset \mathbb{R}^k$, $u : \Omega \to \mathbb{R}$, $f : \Omega \to \mathbb{R}$, $\partial\Omega = \overline{\Omega} \setminus \Omega$ and $\mathbf{x} \in \Omega$, could be found in the form of product of two functions $u(\mathbf{x}) = \omega(\mathbf{x})\Phi(\mathbf{x})$, where the first one is used to **exactly** satisfy the boundary conditions and must possess the following properties:

$$\omega(\mathbf{x}) = 0 \ \text{ on } \partial\Omega, \quad \omega(\mathbf{x}) > 0 \ \text{ in } \Omega, \nabla\omega(\mathbf{x}) \neq 0 \ \text{ on } \partial\Omega,$$

and the second one, to satisfy the differential equation. Kantorovich also showed the solutions for some simple domains like circle and rectangle.

In 1964 Rvachev suggested a method how to build such a functions $\omega(\mathbf{x})$ for almost arbitrary domains with given properties. Thus, having the function $\omega(\mathbf{x})$ for a given domain, we can find $\Phi(\mathbf{x})$ either exactly or approximately in the form $\Phi(\mathbf{x}) \approx \sum_i^n C_i\phi_i(\mathbf{x})$, where $\phi_i(\mathbf{x})$ are known linearly independent basis functions which form a complete sequence in appropriate functional space, but should *not* satisfy the boundary conditions.

In this work the application of RFM to the solution of the Poisson equation with homogeneous Dirichlet boundary conditions in complicated 2D geometrical domain is shown. The convergence study includes the comparison of current results with standard finite element solution and the dependence of the number of coordinate functions on the relative error.

Authors would like to thank Prof. Lydia Kurpa, Prof. Andreas Griewank and Priv. Doz. Lutz Recke for helpful discussions.

IC/PP3163/013: Development of a 2D RBF image reconstruction toolbox for sharp edged images.

Presenter: Vincent Durante (University of Massachusetts, USA)
Co-author: Jae-Hun Jung (Univ. Massachusetts at Dartmouth, USA)

Radial basis functions are widely used for image reconstruction because of grid flexibility and the fast convergence of their approximations; in other words, the RBF methods are mesh-free and high order convergent. We will present the 2D image reconstruction based on radial basis function reconstruction for sharp edged images using a MATLAB toolbox as a GUI interface. Sharp edged images reconstructed using RBF interpolations, however, tend to yield Gibbs ringing effects on the images themselves.

To minimize Gibbs oscillations, the epsilon-adaptive method is employed in the developed GUI toolbox with which the shape parameter is adaptively chosen such that only the first order basis function is used near the neighborhood. To adopt this method, the functions called from the toolbox first detect the discontinuities in the image. The expansion coefficients and the concentration function derived from the first derivatives are used for the generation of an edge map. This edge map is defined where the product of the expansion coefficients and

the concentration functions yield high values.
We also use a domain splitting technique to develop the fast reconstruction algorithm. This technique is also used for the local image reconstruction near the discontinuity, which will be of the most interest to the user. We will present the RGB color image demonstrations using the toolbox. The non-uniform distribution in the reconstructed grid space and the Fourier filtering technique embedded in the toolbox will also be discussed.

02: Numerical Analysis, Minisymposia

IC/MP346/002: Model reduction: theory, methodology and software.

Organiser: Volker Mehrmann (TU Berlin, Germany)
Co-organiser: Zhaojun Bai (UC Davis, USA)
Co-organiser: Roland Freund (UC Davis, USA)

Model order reduction is currently one of the fundamental research areas in simulation and control of large-scale systems. Despite recent progress in the development of Krylov subspace methods, SVD-based methods, and POD methods, in most practical applications there is a discrepancy between fast and efficient methods to compute the reduced order model, preservation of physical properties of the system, like conservation laws, stability, passivity, or variational properties of the system.

There is a lot of research activity in this direction and it is the aim of this minisymposium to bring some of the key players in academia and industry together, to exchange the latest developments and to coordinate research activities. We focus on new and more efficient model reduction techniques, the theoretical foundations and new software developments.

Model reduction for robust control of large-scale systems. **Peter Benner** (TU Chemnitz, Germany) IC/MT1055/002

In this talk we consider the problem of robust control design for systems arising from the semi-discretization of parabolic evolution equations. Following the design methodology of H_∞ control, the usual two model reduction paths can be taken: reduce the plant, then design the controller or design a controller, then reduce it. In the first approach it is necessary to use model reduction techniques that guarantee the robust performance of the controller applied to the original system while for the second approach, it is desirable that the controller reduction preserves the performance (H_∞ norm bounds) of the controller. For these purposes, we will discuss techniques based on bounded-real and H_∞ balancing. We will demonstrate how they can be implemented for large-scale systems arising from finite differences or finite element disrectizations of parabolic control systems such as point and boundary control problems for the heat equation, convection-diffusion and reaction-diffusion equations.

Balancing-related model reduction by a data-sparse cross-Gramian approach. **Ulrike Baur** (TU Chemnitz, Germany), Peter Benner (TU Chemnitz, Germany) IC/MT1079/002

We consider linear time-invariant (LTI) systems of the following form:

$$\Sigma: \begin{cases} \dot{x}(t) &= Ax(t)+Bu(t), \qquad t>0, \qquad x(0)=x^0, \\ y(t) &= Cx(t)+Du(t), \qquad t\geq 0, \end{cases}$$

with stable state matrix $A \in R^{n\times n}$ and $B \in R^{n\times m}$, $C \in R^{p\times n}$, $D \in R^{p\times m}$, arising, e.g., from the discretization and linearization of parabolic PDEs. Typically, in practical applications, we have a large state-space dimension $n = \mathcal{O}(10^5)$ and a small input and output space, $n \gg m, p$. We further assume that the system is square; i.e., $p = m$.

We show how to compute an approximate reduced-order system $\hat{\Sigma}$ of order $r \ll n$ with a balancing-related model reduction method. The method is based on the computation of the cross-Gramian X, which is the solution of the Sylvester equation

$$AX + XA + BC = 0.$$

As standard algorithms for the solution of Sylvester equations are of limited use for large-scale systems, we investigate approaches based on the matrix sign function method. To make this iterative method applicable in the large-scale setting, we propose a modified iteration scheme for computing low-rank factors of the solution X and we incorporate structural information from the underlying PDE model into the approach. By using data-sparse matrix approximations, hierarchical matrix formats, and the corresponding formatted arithmetic we obtain an efficient solver having linear-polylogarithmic complexity. We show that the reduced-order model can then be computed from the low-rank factors directly.

Fast and stable solution of the Stein equation. **Ming Gu** (UC Berkeley, USA) IC/MT3603/002

We develop a fast and stable variant of the Hammarling Algorithm for solving the Stein equation in input-normal form. We present numerical experiments to confirm that it can be significantly faster than the Hammarling Algorithm.

Balanced truncation model reduction for the Oseen equations. **Danny Sorensen** (Rice University, USA), Matthias Heinkenschloss (Rice University, USA), Kai Sun (Rice University, USA) IC/MT4106/002

We discuss balanced truncation model reduction for the semidiscrete Oseen equations with time independent advection. These equations are related to linearized Navier-Stokes equations, so this model problem is relevant to many flow systems where the behavior of the linearized flow around a steady state is of interest. Balanced model reduction for linear time invariant systems is a scheme that preserves asymptotic stability and also provides an error bound on the discrepancy between outputs of the full and reduced order systems. The semidiscrete Oseen equations are a system of differential algebraic equations. Standard balanced truncation model reduction must be adapted to this descriptor system. The algorithm presented here offers a more direct approach than existing methods. In particular, no explicit projection operators are applied and a saddle point solver for Stokes-like linear systems is all that is required for implementation.

Model reduction from input/output measurements. **Athanasios Antoulas** (Rice University, USA) IC/MT4118/002

In many applications no explicit model of a given process is available. Instead input/output measurments of the process exist. The problem therefore consists in computing an appropriate approximate (reduced-order) model directly from these measurements. In this talk we will propose a method for achieving this objective. The main tool is the Loewner matrix. We will also show that this method can be extended to deal with passivity preserving model reduction. Numerical experiments verifying the theoretical considerations will also be provided.

A Krylov-based descent algorithm for optimal H^2 model reduction. **Serkan Gugercin** (Virginia Tech, USA), Christopher Beattie (Virginia Tech, USA) IC/MT4134/002

In this work, we introduce a Krylov-based descent algorithm for optimal H^2 approximation of large-scale dynamical systems where the interpolation points are the variables of the underlying optimization problem. After deriving the gradient and Hessian of the H^2 cost function with respect to interpolation points, a numerically effective optimal H^2 model reduction method is developed. Convergence properties and effectiveness of the algorithm are presented through numerical examples.

Interpolatory projection methods for structure-preserving model reduction. **Christopher Beattie** (Virginia Tech, USA), Serkan Gugercin (Virginia Tech, USA) IC/MT4186/002

We present a framework for interpolatory model reduction that includes rational Krylov-based methods as a special case. This broader framework allows retention of special structure in the reduced order models such as symmetry, second order structure, internal delays, and infinite dimensional subsystems. A rational strategy within this framework for the selection of interpolation points that produce near optimal $\mathcal{H}_\infty$ performance is also presented. Numerical examples are provided to illustrate and support the analysis.

How to solve realistic large-scale saddle-point problems. **Beresford Parlett** (University of California, Berkeley, USA), Jörg Liesen (TU Berlin, Germany) IC/MT4299/002

The coefficient matrix may be written $(AB'; B - C)$ in Matlab notation. A is symmetric positive definite, while C is only semidefinite. In some applications $C = O$. We give necessary and sufficient conditions to be able to solve the system with a CG iteration with a fancy, but economical, inner product. However in realistic applications these conditions are violated because $\|B\|$ is too big. We explore what happens when the inner product becomes indefinite and a look-ahead CG iteration copes with near breakdowns.

IC/MP181/015: Multiscale methods for strongly-heterogeneous media.

Organiser: Assyr Abdulle (University of Edinburgh, UK)

This minisymposium is concerned with the modeling and the numerical simulation of physical processes in strongly heterogeneous media as deformation or diffusion in heterogeneous material, flow in porous medium to mention but a few. A common aspect of these problems is that direct microscopic approaches resolving the heterogeneities of the media are often computationally intractable, due to the high number of degrees of freedom. Macroscopic approaches which do not take into account the fine scale physics are of limited interest, since the microscopic heterogeneities significantly affect the properties of the solution at all scales. There is a growing interest in computational techniques and simulation capable of extracting the effective macroscopic behavior of physical systems in heterogeneous media without resolving all the fine scale details. In this minisymposium key questions as adaptive modeling, efficient coupling of micro-to-macro methods, numerical control of hybrid methods, computational complexity of hierarchical numerical methods as well as some challenging applications will be discussed.

On local microscale problem in multiscale modeling. **Xingye Yue** (University of Science and Technology of China) IC/MT1807/015

Many multiscale methods for strongly heterogeneous media are based on the idea of extracting macroscopic information by solving an array of microscale models over small domains. A key ingredient in such multiscale methods is the boundary condition and the size of the computational domain over which the microscale problems are solved. We will discuss the effects of different boundary conditions and the local cell size for strongly heterogeneous media.

Heterogeneous multi-scale methods for epitaxial growth. **Björn Engquist** (University of Texas at Austin, USA) IC/MT3205/015

Continuum simulations of solids or fluids for which some atomistic information is needed are typical example of multiscale problems with wide ranges of scales. The heterogeneous multi-scale method is a framework for numerical methods that couple computations from very different scales. Local micro-scale simulations on small domains supply missing data to a macro-scale simulation on the full domain. In our example of epitaxial crystal growth, local kinetic Monte Carlo computations produce data to a continuum macro-scale level-set model for island growth.

Homogenization for mesocale oceanic transport and molecular motors. **Peter Kramer** (Rensselaer Polytechnic Institute, USA), Grigorios Pavliotis (Imperial College London, UK), Shafer Smith (New York University, USA), Juan Latorre (Rensselaer Polytechnic Institute, USA), Banu Baydil (Rensselaer Polytechnic Institute, USA) IC/MT3154/015

Two applications of the homogenization procedure will be presented. The first concerns the parameterization of the effects of mesoscale coherent structures on the transport of physical fields in the ocean. We are developing our parameterization procedure from the bottom up, beginning with rather simple mathematical models and combining them with numerical solutions of the cell problems and asymptotic analysis with respect to physical parameters such as Peclet number, Strouhal number, and relative mean flow strength in an attempt to achieve an efficient scheme for relating the large-scale transport to the physical properties of the subgrid structures. At present, the velocity field is treated kinematically.

The second application concerns the use of the homogenization theory to compute transport properties of molecular motors, which we treat within the mathematical framework of "Brownian motors." We examine in particular, through numerical computation and asymptotic analysis, how the effective drift as well as the coherence of transport (as represented by a

Peclet number) behave with respect to the underlying physical parameters of the forces and motor driving time scales. We are also particularly concerned with efficient numerical means of solving the equations produced by the cell problems.

IC/MP181/015: Multiscale methods for strongly-heterogeneous media. #2

(For abstract, see session #1 above.)

Sparse adaptive FEM for multiple-scale problems. **Christoph Schwab** (ETH Zürich, Switzerland) IC/MT1910/015

Elliptic homogenization problems in a domain $\Omega \subset R^d$ with $n+1$ separated scales are reduced to elliptic one-scale problems in dimension $(n+1)d$ using multiscale convergence techniques of G. Allaire and M. Briane. The $(n+1)d$ dimensional, one-scale limit problems are discretized by a sparse tensor product finite element method (FEM) in the physical domain and all 'cells'. We prove that the resulting FEM has accuracy, work and memory requirement comparable to standard FEM for single scale problems in Ω while it gives numerical approximations of the correct homogenized limit as well as of all first order correctors, throughout the physical domain with performance independent of the physical problem's scale parameters and the full approximation order in terms of the number N of degrees of freedom in the physical domain Ω.

Condition numbers of the discrete problems are bounded uniformly in the number of scales as well as in the scale parameters.

Joint work w. V. H. Hoang (Cambridge) and R. Stevenson (Utrecht).

An analytical framework for the numerical homogenization of integral functionals. **Antoine Gloria** (Ecole Nationale des Ponts et Chaussées, France) IC/MT1553/015

We present one possible analytical framework to clarify some convergence properties of numerical homogenization schemes to deal with heterogeneous media. This approach completes previous results existing in the literature. The problem under consideration is the minimization of a nonlinear integral functional, both in the convex and quasiconvex settings, with and without spatial assumptions such as periodicity or stochasticity. This approach relies on variational calculus and Γ-convergence. It allows to address some aspects of nonlinear elasticity such as the frame invariance property. We also address the issue of convergence of the numerical correctors for monotone elliptic operators without assumption on the structure of the heterogeneities, and we provide some new error estimates in the periodic case.

Analysis of multiscale methods: methodology and examples. **Pingbing Ming** (Chinese Academy of Sciences), Pingwen Zhang (Peking University, PR China), Xingye Yue (University of Science and Technology of China) IC/MT2060/015

Analysis of multiscale methods presents a challenge to numerical analyst, particularly for problems involving multi-physics. The heterogeneous multiscale method gives a general framework for the analysis of multiscale methods besides providing guidelines for the design of the method. In this talk, I will demonstrate this by applying the framework to two canonical problems: partial differential equations with multiscale coefficients as well as the local quasicontinuum methods.

This is a joint work with Weinan E (PACM, Princeton University), Pingwen Zhang (University of Beijing) and Xingye Yue (University of Science and Technology).

Finite-element heterogeneous multiscale methods with near-optimal computational complexity. **Assyr Abdulle** (University of Edinburgh, UK), Björn Engquist (University of Texas at Austin, USA) IC/MT2752/015

Macro-to-micro numerical methods have become increasingly popular for the multiscale modelling of problems often impossible to solve by direct numerical simulations.

In this talk we discuss macro-to-micro finite element methods constructed in the framework of the heterogeneous multiscale method (HMM). The global behaviour of such methods depends on the hierarchy of solvers and on the strategy to couple them. A fully discrete analysis is crucial for the understanding of error propagation across scales and the global complexity is in general superlinear in the macro degrees of freedom. In this talk we discuss how to couple macro methods with fast micro solvers in order to achieve near optimal computational complexity for finite element heterogeneous multiscale methods.

IC/MP802/015: Verified computations with applications.

Organiser: Siegfried Rump (TU Hamburg-Harburg, Germany)
Co-organiser: Shinichi Oishi (Waseda University, Japan)

Recently, the research in the field of verified numerical computations has made great progress. This minisymposium focuses on recent advances and gathers 8 papers from 5 countries, namely Japan, three countries in Europe and USA.

Starting from the presentation of recent results on highly accurate and fast summation algorithms, presentations for algorithms for numerical verification of geometric predicates and fast and accurate polynomial evaluation based on these summation algorithms will follow. Then, constraint global optimization with verification of the result will be discussed within a general framework of computer assisted proofs. As concrete examples of computer assisted proofs, scattering problems of sound and light, numerical existence and uniqueness theorems for PDEs and bifurcation problems will be treated. Finally, relations and applications to fuzzy logic will also be discussed.

This variety of talks will elucidate the state of arts of the rapidly developing research field on verified numerical computations.

Error bounds for extremely ill-conditioned problems. **Siegfried Rump** (TU Hamburg-Harburg, Germany) IC/MT2960/015

We discuss methods to compute error bounds for extremely ill-conditioned problems. As a model problem we treat matrix inversion. We demonstrate that additive corrections to improve an approximate inverse are useful for ill-conditioned problems, but hardly usable for extremely ill-conditioned problems. Here multiplicative corrections can be used, including the possibility to compute guaranteed error bounds. Problem with condition numbers 1e100 and more are solved in double precision.

Fast and accurate floating-point summation. **Takeshi Ogita** (Japan Science and Technology Agency), Siegfried Rump (TU Hamburg–Harburg, Germany), Shinichi Oishi (Waseda University, Japan) IC/MT2799/015

Recently, we proposed a new accurate summation algorithm. For a floating-point vector p, the algorithm returns a result faithfully rounded from the exact summation of p. Moreover, it is very fast in terms of not only flop counts but also measured computing time. In this talk, we try to make the algorithm speed up further. For the purpose, we use a grouping of the elements in p without any sorting. The summation algorithm with our speedup method is faster than or at worst equal to the original one. The speedup method does not change any analysis for the summation algorithm, i.e. it returns exactly the same (faithful) result as that from the original one. The effectiveness of the speedup method strongly depends on how the data of various magnitude are distributed in p.

First in the talk, we briefly review our new accurate summation algorithm. Next, we explain how to speedup the algorithm. Finally, numerical results are presented showing performance of the proposed speedup method.

Faithful Horner algorithm. **Philippe Langlois** (Université de Perpignan, France), Nicolas Louvet (Université de Perpignan, France) IC/MT3342/015

Compensated Horner algorithm consists in correcting the rounding errors generated by floating point computation of the classic Horner algorithm for polynomial evaluation. Using what Rump, Ogita and Oishi named error free transformations in [1], the compensated Horner algorithm is proved to be as accurate as the Horner algorithm computed with twice the current precision. Iterating such correction we also provide another compensated Horner algorithm proved to be as accurate as the Horner algorithm performed in k times the working precision. These compensated algorithms are fast and compare favorably with double-double or quad-double corresponding implementations. We will present new results about this compensated Horner algorithm that allow us to efficiently compute a *faithful polynomial evaluation*, that is to return one of the two nearest floating point numbers that enclose the exact polynomial evaluation. [1] Ogita, T., Rump S.M. and Oishi S.; *Accurate sum and dot product*, SIAM J. Sci. Comput., 26(6):1955:1988, 2005.

Fast and adaptive algorithm for 2D orientation problem. **Katsuhisa Ozaki** (Waseda University, Japan), Takeshi Ogita (Japan Science and Technology Agency), Siegfried Rump (TU Hamburg–Harburg, Germany), Shinichi Oishi (Waseda University, Japan) IC/MT4951/015

This talk is concerned with the computational geometry. A number of geometric problems can be boiled down to the determinant predicates, i.e. whether the sign of the determinant is positive, negative or zero. In particular, we focus our mind on the 2D orientation problem ORIENT2D, which determines whether a point is exactly on a line or on which side it is in two dimensional space. If the point is close to the line, one may obtain an incorrect result due to rounding errors by usual floating-point computations. To solve such ill-conditioned cases, some higher precision is necessary. On the other hand, it is not efficient to use higher precision arithmetic for well-conditioned cases.

In this talk, we propose a fast, robust and adaptive algorithm of solving ORIENT2D based on a new accurate summation algorithm which is developed by the latter three authors (S. M. Rump, T. Ogita and S. Oishi). If given points are represented by floating-point numbers, the computation of determinant can be transformed into a computation of summation without rounding errors. Since their algorithm can verify an accuracy of the obtained result, the sign of the determinant can also be guaranteed. By specializing their algorithm for the computation of the determinant with considering the structure of data for floating-point summation and devising a way of its implementation, computational cost for solving ORIENT2D can efficiently be reduced. Moreover, to make an adaptive algorithm is also possible, i.e. its computational cost increases gradually according to the difficulty of a given problem.

Finally, some numerical results are presented showing that our proposed algorithm is faster than the state-of-the-art one by Shewchuk's one in many cases.

Verified global optimization with GloptLab. **Ferenc Domes** (Universität Wien, Austria), Arnold Neumaier (Universität Wien, Austria) IC/MT3426/015

We present GloptLab, a MATLAB toolbox for the verified global optimization of quadratic functions with quadratic constraints. The main tools used are local optimization, semidefinite programming, branch and bound, interval analysis and constraint programming. Powerful new techniques allow many problems to be solved with a comparatively small branch tree. For potential applications to computer-assisted proof, some emphasis is given to generate a list of certificates that enables a simple proof checker to verify the validity of the global optimum with mathematical rigor, and a human readable version of the proof outline, with links to more details as far as desired.

On constructive a priori *and* a posteriori *error estimates for the finite-element approximations of non-coercive elliptic problems.* **Mitsuhiro Nakao** (Kyushu University, Japan), Kouji Hashimoto (Kyoto University, Japan) IC/MT2100/015

On the finite element method for noncoercive linear elliptic boundary value problems, there are no existing techniques to get *a priori* and/or *a posteriori* error estimates. For such kind of problems, we have to know the invertibility of concerning elliptic operators. In this talk, by using the invertibility condition which was established by the authors, we present a method enabling us to determine the actual constant appearing in the *a priori* error etimates even for noncoercive case. We also give an efficient method to obtain *a posteriori* error estimates for the same problem. These results can also be applied to the *a posteriori* error estimates for solutions of nonlinear elliptic problems. Several numerical examples which confirm the actual usefulness of the method will be presented.

Enclosure methods and computer-assisted proofs for nonlinear elliptic boundary value problems. **Michael Plum** (Universität Karlsruhe, Germany) IC/MT3226/015

The lecture will be concerned with numerical enclosure methods for nonlinear elliptic boundary value problems. Here, analytical and numerical methods are combined to prove rigorously the existence of a solution in some "close" neighborhood of an approximate solution computed by numerical means. Thus, besides the existence proof, verified bounds for the error (i.e. the difference between exact and approximate solution) are provided.

For the first step, consisting of the computation of an approximate solution ω in some appropriate Sobolev space, no error control is needed, so a wide range of well-established numerical methods (including multigrid schemes) is at hand here. Using ω, the given problem is rewritten as a *fixed-point equation* for the error, and the goal is to apply a *fixed-point theorem* providing the desired error bound.

The conditions required by the chosen fixed-point theorem (e.g., compactness or contractivity, inclusion properties for a suitable subset etc.) are now verified by a combination of analytical arguments (e.g. explicit Sobolev embeddings, variational characterizations etc.) and verified computations of certain auxiliary terms, in particular of eigenvalue bounds for the linearization of the given problem at ω.

The method is illustrated by several examples (on bounded as well as on unbounded domains), where in particular it gives existence proofs in cases where no purely analytical proof is known.

Numerical uniqueness and existence theorem for solution of Lippmann–Schwinger equation to 2D sound-scattering problem. **Shinichi Oishi** (Waseda University, Japan) IC/MT2792/015

In this paper, we are concerned with a scattering problem for the Helmholtz equation in the inhomogeneous media. It is well known that this problem is given as a mathematical modeling of a two dimensional sound scattering problem.

In this talk, for the sake of simplicity, we treat the case that the problem have a smoothness $W^{\mu,2}(\mathbb{R}^2)$, $\mu \geqq 3/2$ and present Theorem giving a sufficient condition of guaranteeing that the homogeneous equation corresponding to the original equaiton has in H^0 only the trivial solution. A remarkable feature of this theorem is that the sufficient condition shown in this theorem can be evaluated by verified numerical computations. Furthermore, if such a sufficient condition holds, it also gives an upper bound of $\|(I - aK)^{-1}\|_{\mathcal{L}(H^0)}$ and a tight error bound between the exact solution v and an approximate solution $\tilde{v}$ which is generated by computer. As a result, this paper is to present a numerical uniqueness and existence theorem for the problem, which asserts the existence of a unique solution around an approximate solution computed by numerical calculation.

IC/MP333/020: Large-scale eigenvalue problems.

Organiser: Peter Arbenz (ETH Zürich, Switzerland)

Recent years have seen the emergence of a number of new algorithms for the solution of large scale eigenvalue problems. Large scale eigenvalue problems are so big that the involved matrices can not be factored such that a standard shift-and-invert Lanczos algorithm is not a suitable solution method. The speakers of this minisymposium will discuss ways to overcome this problem presenting Arnoldi-/Lanczos-like, versions of Davidson/Jacobi–Davidson and Locally Optimal Block Preconditioned Conjugate Gradient (LOBPCG) Algorithm to solve large eigenvalue problems from science and engineering.

Enhancements to the PRIMME eigenvalue package and recent experimental results. **Andreas Stathopoulos** (College of William and Mary, USA) IC/MT2033/020

PRIMME, or PReconditioned Iterative MultiMethod Eigensolver, is a comprehensive, open source software package for solving large, sparse, Hermitian eigenvalue problems. While implementing advanced, near optimally converging methods, it has a very simple interface that requires little, or no parameter tuning. Moreover, our new DYNAMIC algorithm, alternates between methods to find the best at runtime. We review this and other PRIMME enhancements, and present experimental results from a variety of application areas that demonstrate PRIMME's superior robustness and efficiency over other state-of-the-art eigenvalue software.

*Block locally-optimal pre-conditioned eigenvalue xolvers (*BLOPEX*).* **Andrew Knyazev** (University of Colorado at Denver, USA) IC/MT3644/020

Block Locally-Optimal Preconditioned Eigenvalue Xolvers (BLOPEX) is a package, written in C, that at present includes only one eigenxolver, Locally Optimal Block Preconditioned Conjugate Gradient Method (LOBPCG). BLOPEX supports parallel computations through an abstract layer. BLOPEX is incorporated in the HYPRE package from LLNL and is availabe as an external block to the PETSc package from ANL as well as a stand-alone serial library. Hypre and PETSc packages provide high quality multigrid and domain decomposition preconditioning on parallel clusters with distributed or shared memory architecture.

The LOBPCG method, suggested and developed by Andrew Knyazev [1] in the past decade, recently attracts an increasing attention as a potential alternative to the shift-and-invert Lanczos and preconditioned Davidson methods due to its simplicity, robustness and fast convergence. Several MATLAB, C, C++ and FORTRAN implementations of the LOBPCG are developed by different groups, e. g., for such applications areas as structured mechanics and electronic structure calculations.

Main LOBPCG features: a matrix-free iterative method for computing several extreme eigenpairs of symmetric positive generalized eigenproblems; a user-defined preconditioner; robustness with respect to random initial approximations, variable preconditioners, and ill-conditioning of the stiffness matrix; apparently optimal convergence speed.

We present initial scalability results using BLOPEX with Hypre and PETSc on one BlueGene/L box solving eigenvalue problems of record sizes.

Robust expansion of subspaces in iterative projection methods. **Heinrich Voss** (TU Hamburg–Harburg, Germany) IC/MT1064/020

Iterative projection methods for large eigenproblems have proven to be very efficient if a small number of eigenvalues and eigenvectors are desired. Here the eigenproblem is projected to a subspace of small dimension which yields approximate eigenpairs. If an error tolerance is not met then the search space is expanded in an iterative way with the aim that some of the eigenvalues of the reduced matrix become good approximations of some of the wanted eigenvalues of the given large matrix.

Expanding the subspace by the Jacobi-Davidson method is very efficient. It is known to converge at least quadratically if the correction equation is solved exactly, and it is common experience that the fast convergence is maintained if the correction equation is solved only approximately. In this talk we derive the Jacobi–Davidson method in a way that explains this robust behavior.

Iterative computation of band edge states for semi-conductor nano structures. **Christof Voemel** (Lawrence Berkeley National Laboratory, USA) IC/MT2591/010

The so-called band edge states determine optical and electronical properties of semi-conductor nano structures. They can be computed from an interior eigen-problem. We study the robustness and performance of state-of-the-art iterative eigensolvers on large quantum dots and wires, focusing on variants of preconditioned CG, Lanczos, and Davidson methods.

IC/MP333/020: Large-scale eigenvalue problems. #2

Organiser: Peter Arbenz (ETH Zürich, Switzerland)

(For abstract, see session #1 above.)

A Jacobi–Davidson algorithm for large eigenvalue problems from opto-electronics. **Peter Arbenz** (ETH Zürich, Switzerland) IC/MT3641/020

The construction of prototypes of nowadays opto-electronic components during their development is very expensive. Therefore, they are developed and simulated on the computer. This procedure admits to determine and optimize their characteristics, in particular their optical characteristics, in advance. The progressive miniaturization of opto-electronic components leads to numerous quantum-mechanical effects, that cannot be treated by the usual classical models. Quantum-mechanical methods have to be employed. The states of the charge carriers and the dispersion relations are determined by coupled Schrödinger equations. Their discretization by means of the finite element method leads to large sparse generalized complex Hermitian eigenvalue problems. Because of their size the solution of these eigenvalue problems requires sophisticated eigensolvers. We present a variant of the Jacobi–Davidson (JD) algorithm that is based on a real symmetric formulation of the complex Hermitian eigenvalue problem. The correction equations that have to be solved in each step of JD are solved by the conjugate gradient algorithm preconditioned by a V-cycle of smoothed aggregation multigrid.

On large-scale diagonalization techniques for the Anderson model of localization. **Olaf Schenk** (Universität Basel, Switzerland), Matthias Bollhöfer (TU Braunschweig, Germany) IC/MT1227/020

We propose efficient preconditioning algorithms for an eigenvalue problem arising in quantum physics, namely the computation of a few interior eigenvalues and their associated eigenvectors for large-scale sparse real and symmetric indefinite matrices of the Anderson model of localization. We compare the Lanczos algorithm in the 1987 implementation by Cullum and Willoughby with the shift-and-invert techniques in the implicitly restarted Lanczos method and in the Jacobi–Davidson method. Our preconditioning approaches for the shift-and-invert symmetric indefinite linear system are based on maximum weighted matchings [1] and algebraic multilevel incomplete LDL^T factorizations. These techniques can be seen as a complement to the alternative idea of using more complete pivoting techniques for the highly ill-conditioned symmetric indefinite Anderson matrices. We demonstrate the effectiveness and the numerical accuracy of these algorithms. Our numerical examples reveal that recent algebraic multilevel preconditioning solvers can accelerate the computation of a large-scale eigenvalue problem corresponding to the Anderson model of localization by several orders of magnitude[2].

This is joint work with Matthias Bollhöfer (TU Brunswick) and Rudolf Römer (University of Warwick).

Polynomial-filtered Lanczos iterations with applications in electronic-structure calculations. **Konstantinos Bekas** (IBM Zurich Research Laboratory, Switzerland), Yousef Saad (University of Minnesota, USA) IC/MT1445/020

The most expensive part of all Electronic Structure Calculations based on Density Functional Theory, lies in the computation of an invariant subspace associated with some of the smallest eigenvalues of a discretized Hamiltonian operator. The dimension of this subspace typically depends on the total number of valence electrons in the system, and can easily reach hundreds or even thousands when large systems with many atoms are considered. At the same time, the discretization of Hamiltonians associated with large systems yields very large matrices, whether with plane-wave or real space discretizations. The combination of these two factors results in one of the most significant bottlenecks in Computational Materials Science. In this paper we show how to efficiently compute a large invariant subspace associated with the smallest eigenvalues of a symmetric/hermitian matrix using polynomially filtered Lanczos iterations. The proposed method does not try to extract individual eigenvalues and eigenvectors. Instead, it constructs an orthogonal basis of the invariant subspace by combining two main ingredients. The first is a filtering technique to dampen the undesirable contribution of the largest eigenvalues at each matrix-vector product in the Lanczos algorithm. This technique employs a well-selected low-pass filter polynomial, obtained via a conjugate residual-type algorithm in polynomial space. The second ingredient is the Lanczos algorithm with partial reorthogonalization. Experiments are reported to illustrate the efficiency of the proposed scheme compared to state-of-the-art implicitly restarted techniques.

Solving large-scale nonlinear eigenvalue problems in electronic-structure calculation. **Chao Yang** (Lawrence Berkeley National Laboratory, USA) IC/MT3108/020

One of the fundamental problems in electronic structure calculation is to determine electron orbitals associated with the minimum total energy of large atomistic systems. The total energy minimization problem is often formulated as a nonlinear eigenvalue problem and solved by an iterative scheme called Self Consistent Field (SCF) iteration. In this talk, a new direct constrained optimization algorithm for minimizing the Kohn-Sham (KS) total energy functional is presented. The key ingredients of this algorithm involve projecting the total energy functional into a sequences of subspaces of small dimensions and seeking the minimizer of total energy functional within each subspace. The minimizer of the projected energy functional not only provides a search direction along which the KS total energy functional decreases but also gives an optimal "step-length" to move along this search direction. Due to the small dimension of the projected problem, the minimizer of the projected energy functional can be computed by several different methods. These methods will be examined and compared in this talk. Numerical examples will be provided to demonstrate that this new direct constrained optimization algorithm can be more efficient and robust than the SCF iteration.

IC/MP277/020: Tensor decompositions and their application.

Organiser: Brett Bader (Sandia National Laboratories, USA)
Co-organiser: Tamara Kolda (Sandia National Laboratories, USA)

Tensors, also known as multidimensional, multi-way, or n-way arrays, are higher-order analogues of matrices. The Tucker and CANDECOMP/PARAFAC (CP) tensor decompositions were introduced more than three decades ago in the context of psychometrics and can be thought of as generalizations of the matrix singular value decomposition (SVD). The Tucker and CP tensor decompositions have since proven useful in a variety of fields including chemometrics, signal processing, computer graphics, statistics, etc. Using multilinear algebra rather than standard linear algebra has the advantage of yielding, in many cases, smaller and more meaningful factorizations. Moreover, it may not be necessary to impose orthogonality to yield uniqueness.

The Tucker and CP tensor decompositions are closely related to methods that exploit Kronecker or Khatri–Rao product structure in matrices. In this session, the speakers will present extensions of the Tucker and CP tensor decompositions to nonnegative and block (i.e., a combination of Tucker and CP) tensor factorizations. Additionally, the session will highlight algorithmic and computational aspects of handling large-scale, sparse, noisy, and/or missing data for applications in chemistry, medicine, network analysis, and data mining. The first presentation will provide an overview of tensor decompositions and their relevance.

The decomposition in rank-$(L, L, 1)$ terms: an approach based on simultaneous matrix diagonalization. **Lieven De Lathauwer** (CNRS-ETIS, France) IC/MT1879/012

The Canonical decomposition or Parallel factor decomposition (CP) in multilinear algebra is the decomposition of a higher-order tensor in a sum of rank-1 terms. Contrary to the Singular Value Decomposition of matrices, CP is unique without imposing orthogonality conditions on the factors. Uniqueness is guaranteed under the so-called 'Kruskal condition'.

Recently we have considered the case of 'long' tensors, i.e., tensors of which one of the dimensions is greater than the rank. For such tensors, we have derived a uniqueness condition that is much more relaxed than Kruskal's. The proof of the theorem is constructive. It shows that, for exact data, CP follows from the Eigenvalue Decomposition (EVD) of a matrix. For noisy data we have proposed an algorithm based on a simultaneous matrix decomposition.

Recently, we have also proposed a generalization of CP in which each term consists of the outer product of a vector and a rank-L matrix, L being relatively small but greater than one. Uniqueness is guaranteed under Kruskal-type conditions.

In this talk we will combine the two new ideas. That is : (1) we will show that, in the case of exact data, the decomposition in rank-(L,L,1) terms of a long tensor follows from a matrix EVD, (2) for noisy data, we will propose an algorithm based on a simultaneous matrix decomposition, (3) we will present new sufficient conditions for uniqueness that are significantly more relaxed than the Kruskal-type conditions.

Blind source separation and automatic transcription of music using tensor decompositions. **Derry FitzGerald** (Cork Institute of Technology, Ireland) IC/MT416/012

Tensor decompositions have recently found use in the sound source separation and automatic transcription of musical recordings. The majority of musical recordings available are stereo recordings created by linear mixing of single channel recordings of different instruments, with different gains in each channel to create a stereo image. Non-negative tensor decomposition is carried out on a tensor containing magnitude spectrograms of each channel of the input signals, yielding sets of basis functions corresponding to aspects of the musical recording, such as a note played by a musical instrument. These basis functions can then be grouped together by source, allowing the creation of a magnitude spectrogram containing information related to a single sound source. Grouping of the basis functions can be done using a variety of criteria, such as statistical dependencies between basis functions, or grouping by similar gain patterns across the channels. However, in many cases, it is difficult to automatically assign the basis functions to sources.

This grouping problem can be overcome by incorporating frequency shift invariance into the tensor decomposition model. This allows notes played by an instrument to be modeled as translations of a single instrument basis function, thereby eliminating the need to cluster the basis functions. Further, as the timbre of musical instruments evolve with time, a single basis function cannot capture this time evolution. This can be modeled by adding time shift invariance to the model, resulting in a musical instrument being modeled as a spectrogram that is translated in frequency to correspond to different notes played by the instrument. A transcription of the notes played by a given instrument can then be obtained from the activations of each translation of that instrument. This demonstrates the utility of a tensor decomposition approach, in that both sound source separation and automatic transcription are obtained simultaneously.

Tensor decompositions in chemistry. **Giorgio Tomasi** (Københavns Universitet, Denmark) IC/MT2759/012

Nowadays, many common analytical instruments and chemical problems generate $N-$way data arrays (for $N > 2$) whose systematic part is well described by so-called multilinear models; for this reason such models are growing increasingly popular in chemometrics. This presentation will focus on three of them: the PARAFAC (from 'PARAllel FACtors') model, which is essentially a best low-rank approximation of the data tensor; the $N-$way Tucker model, which is akin to the Singular Value Decomposition for matrices, and, for regression problems, the nPLS model, which is an extension of Partial Least Squares regression.

The use of such models on chemical data will be illustrated by means of practical examples together with some details on the state of the art on fitting algorithms and on open theoretical and practical challenges associated with them.

The Matlab tensor toolbox for efficient computations with sparse and factored tensors. **Tamara Kolda** (Sandia National Laboratories, USA), Brett Bader (Sandia National Laboratories, USA) IC/MT1478/012

This talk considers tensors with special structure and how their structure might be exploited for efficient storage and computation. Sparse tensors have the property that the vast majority of the elements are zero. We propose storing such tensors using coordinate format and consider the computational efficiency of this scheme for mathematical operations typical of those used in tensor decomposition algorithms. Factored tensors have the property that they can be assembled from components. We consider two specific types: a Tucker tensor can be expressed as the product of a core tensor (which itself may be dense, sparse, or decomposed) and a matrix along each mode, and a Kruskal tensor can be expressed as the sum of rank-1 tensors. We are interested in the case where the storage of the components is less than the storage of the full tensor and demonstrate that many elementary operations can be computed using only the components. All of the efficiencies described in this talk are implemented in the Tensor Toolbox for MATLAB.

IC/MP277/020: Tensor decompositions and their application. #2

Organiser: Brett Bader (Sandia National Laboratories, USA)
Co-organiser: Tamara Kolda (Sandia National Laboratories, USA)

(For abstract, see session #1 above.)

An overview of tensor decompositions and their applications. **Brett Bader** (Sandia National Laboratories, USA) IC/MT404/012

This presentation will introduce recent decompositions and applications of tensors (also known as multidimensional, multiway, or n-way arrays). Higher-order tensor decompositions originated in the field of psychometrics more than thirty years ago and have since become a promising technique in chemometrics, image analysis, signal processing, and, more recently, data mining. Researchers from a number of fields have applied tensor decompositions to some exciting applications with convincing results.

By incorporating extra information in higher-order data arrays, tensor decompositions are capable of extracting structure beyond traditional matrix analysis, such as the singular value decomposition (SVD) or principal components analysis (PCA). PARAFAC and the Tucker model are just two tensor decompositions for extracting information for some applications, but even more decompositions exist or are being proposed. Many challenges exist in deriving and applying these decompositions, including determining the proper model for the application, determining the appropriate rank of the approximation, and making any algorithms computationally efficient. As these techniques are applied to ever larger problems, another challenge is to find ways to extend these methods to large-scale data sets, i.e., data sets with thousands to millions of entries. This will require advances in the theory and computation of higher-order tensor decompositions.

This presentation first will introduce the mathematics and algorithms of tensor decompositions from an applied mathematics perspective and, second, will survey some applications across a variety of disciplines.

Sparseness constraints and non-negative tensor decomposition. **Morten Mørup** (Danmarks Tekniske Universitet, Denmark) IC/MT741/012

Higher order matrix (tensor) decompositions are mainly used in psychometrics, chemometrics, image analysis, graph analysis and signal processing. For higher order data the two most commonly used decompositions are the PARAFAC and the TUCKER model. If the data analyzed is non-negative it may be relevant to consider additive non-negative components. Non-negative matrix factorization (NMF) can easily be extended to form algorithms for non-negative TUCKER and PARAFAC decompositions. Furthermore, the PARAFAC model can be extended to account for shift and echo effects in the data by extending concepts from matrix deconvolution to tensors. To improve the uniqueness of the decomposition constraints in the form of the L1 norm is useful. Several algorithms are devised for non-negative decomposition of multi-way data (tensors) and their performance demonstrated on a range of datasets spanning from neuroscience and chemometry to music signals.

Computing the best rank-(R_1, R_2, R_3) approximation of a tensor. **Lars Eldén** (Linköpings universitet, Sweden) IC/MT535/012

We investigate various properties of the best rank-(R_1, R_2, R_3) approximation of a tensor, and their implications in the development of algorithms for computing the approximation. Often alternating methods are used for computing the solution of this problem. We investigate the convergence properties of alternating iteration and present alternative methods with faster convergence, including the variable projection and Newton-Grassmann method.

This is joint work with Berkant Savas.

Understanding epilepsy seizure structure using tensor decompositions. **Evrim Acar** (Rensselaer Polytechnic Institute, USA) IC/MT428/012

Epilepsy surgery outcome strongly depends on the localization of epileptic focus. We address the problem of identification of seizure origin through an analysis of ictal EEG, which is proven to be an effective standard in epileptic focus localization.

With a goal of presenting an automated and robust way of visual analysis of large amounts of EEG data, we construct a multiway EEG data array with three modes, i.e. time samples, scales and electrodes, through wavelet transformation. We then study the performance of multiway analysis techniques, particularly Parallel Factor Analysis (PARAFAC), in understanding the complex structure of epilepsy seizure and localization of seizure origin.

Our preliminary results on patients with temporal lobe epilepsy reveal that multiway analysis techniques are capable of capturing epileptic focus precisely when validated with clinical findings.

IC/MP255/020: Computational methods for structured eigenvalue problems.

Organiser: Peter Benner (TU Chemnitz, Germany)
Co-organiser: Daniel Kressner (Umea University, Sweden)

Linear and nonlinear eigenvalue problems that arise from applications in engineering, chemistry or physics are typically highly structured. Classes of structured matrices that have traditionally been a central issue in numerical linear algebra are symmetric, Hermitian, sparse, Toeplitz, Hankel, Hamiltonian and symplectic matrices, the latter two being related also to the solution of algebraic Riccati equations. Apart from those, new structures have emerged in recent years. These are often connected to linearizations of quadratic or rational eigenproblems. The associated matrix pencils are called even, odd, or palindromic. Currently, the development of numerical algorithms for these new matrix pencil structures is making rapid progress. In many cases, the matrix representations are not only highly redundant but also reflect some physical properties from the original problem. Consequently, the exploitation of these structures can have significant positive effects on the efficiency and accuracy of computational methods and therefore lies at the heart of modern numerical linear algebra. This minisymposium covers several aspects of structured eigenvalue problems, with emphasis on reliable and effective numerical methods.

HAPACK: software for structured eigenvalue problems. **Daniel Kressner** (Umea University, Sweden), Peter Benner (TU Chemnitz, Germany) IC/MT1476/020

HAPACK is a software package containing Fortran and Matlab routines for solving structured eigenvalue problems. This talk introduces version 2.0 of HAPACK extending its functionality significantly. A number of new routines address the computation of eigenvalues and invariant subspaces of matrix products in a numerically backward stable manner. This also allows to cover several classes of generalized eigenvalue problems, including (skew-)Hamiltonian, (skew-)symmetric, and symplectic pencils. For some of these classes, structure-preserving variants of Krylov subspace methods are implemented, providing functionality for large and sparse eigenvalue problems. The aim of this talk is to illustrate the use of HAPACK for practical applications and its benefits compared to general-purpose eigenvalue solvers, as, e.g., implemented in Matlab's eig and eigs commands. This is joint work with other contributors to HAPACK.

Computing the SVD of symplectic matrices. **Niloufer Mackey** (Western Michigan University, USA) IC/MT2825/020

It has recently been shown that every symplectic matrix has a *symplectic SVD*; i.e., an SVD in the usual sense in which each factor is also symplectic. We present a structure-preserving one-sided Jacobi algorithm to compute the symplectic SVD of any $2n \times 2n$ matrix. The method uses at most n^2 iterations per sweep, introducing zeroes via sorting symplectic orthogonal transformations that can be efficiently computed at each iteration. The algorithm is parallelizable, and the convergence rate is asymptotically quadratic.

This is joint work with A. Chaiyakarn.

Sort-Jacobi and generalizations of the symmetric-eigenvalue problem. **Martin Kleinsteuber** (Universität Würzburg, Germany) IC/MT1146/020

In the first part of the talk it is shown how several well-known structured eigenvalue and singular-value problems can be considered as a Lie algebraic generalization of the symmetric eigenvalue problem (EVP). Due to the well known classification of semi-simple Lie algebras, these include the real and complex SVD, hermitian and skew-Hermitian Hamiltonian EVP, the skew-symmetric EVP and Takagi's factorization as well as a Takagi-like factorization and three other interesting non-equivalent EVPs.

In the second part, a structure preserving Sort-Jacobi algorithm is presented to solve the above mentioned structured EVP/SVDs. The proposed method applies to an arbitrary semisimple Lie algebra on its (-1)-eigenspace of the Cartan involution. The proof of local quadratic convergence is sketched.

Structure-preserving doubling algorithms for solving algebraic Riccati-type equations. **Wen-Wei Lin** (National Tsing Hua University, Taiwan) IC/MT1384/020

Based on the doubling algorithm (Anderson 1978, Kimura 1988), we first propose a structure-preserving doubling algorithm (SDA) for computing the symmetric or symmetric positive semi-definite solution to the discrete-time algebraic Riccati equation (DARE), and the symmetric or symmetric positive definite to the nonlinear matrix equation (NME). The SDA algorithm is derived from a new point of view on doubling the associated symplectic pencil $(\mathcal{M}, \mathcal{L})$ while keeping the doubling pencil in a standard symplectic form at each step. We show that SDA converges quadratically if $(\mathcal{M}, \mathcal{L})$ has no unimodular eigenvalues, and it converges linearly with convergence rate 1/2 if all partial multiplicities of unimodular eigenvalues of $(\mathcal{M}, \mathcal{L})$ are even.

Secondly, we develop the SDA algorithm for the computation of the minimal nonnegative solutions to the nonsymmetric algebraic Riccati equation (NARE) and its dual equation, simultaneously. We establish a global quadratic convergence for SDA if the associated Hamiltonian-like M-matrix $\mathcal{K}$ is nonsingular, and a global linear convergence for SDA if the M-matrix $\mathcal{K}$ is irreducible and singular.

Numerical experiments show that the SDA algorithm is reliable, efficient, and outperforms QR-type, Newton-type methods on a set of benchmark problems.

IC/MP255/020: Computational methods for structured eigenvalue problems. #2

Organiser: Peter Benner (TU Chemnitz, Germany)
Co-organiser: Daniel Kressner (Umea University, Sweden)

(For abstract, see session #1 above.)

Numerical solution of eigenvalue problems with symplectic or palindromic structure. **Volker Mehrmann** (TU Berlin, Germany) IC/MT1139/020

We will discuss two different classes of eigenvalue problems (symplectic and palindromic) which have similar spectral properties. We will discuss their relationship and extend known results for symplectic and palindromic eigenvalue problems to matrix pencils and matrix polynomials. We present staircase algorithms for these classes to deflate singular parts and high index parts associated with the eigenvalue ∞.

We will also discuss numerical methods for the deflated prob-

lem that has only finite eigenvalues and semisimple infinite eigenvalues.

This is joint work with Ralph Byers, D. Steven Mackey, and Hongguo Xu

On a quadratic eigenvalue problem arising in the analysis of delay equations. **Heike Faßbender** (TU Braunschweig, Germany) IC/MT1393/020

The analysis of retarded linear m-delay time delay systems

$$\begin{array}{ll} \dot{x}(t) = \sum_{k=0}^{m} A_k x(t-h_k), & t > 0 \\ x(t) = \phi(t), & t \in [-h_m, 0] \end{array}$$

with $h_0 = 0 < h_1 < \ldots < h_m, x : [-h_m, \infty) \to \mathbb{R}^n, A_k \in \mathbb{R}^{n\times n}$, leads to a quadratic eigenvalue problem $Q(\lambda)u = 0$ where

$$Q(\lambda) = \lambda^2 E + \lambda F + G$$

with $E = A_m \otimes I, G = I \otimes A_m$, and $F = \sum_{k=0}^{m-1} I \otimes A_k e^{-i\phi_k} + A_k \otimes Ie^{i\phi_k}, \phi_k = \omega h_k$ where $\otimes$ denotes the Kronecker product. As there exists a permutation matrix P such that $P^T(A \otimes B)P = B \otimes A$ for all real $n \times n$ matrices A, B, the quadratic matrix polynomial Q satisfies

$$P^T rev(\overline{Q}(\lambda))P = Q(\lambda),$$

where $\overline{Q}(\lambda) = \lambda^2\overline{E} + \lambda\overline{F} + \overline{G}$ and $rev(Q(\lambda)) = \lambda^2 Q(\frac{1}{\lambda})$. Here we will discuss properties like eigenvalue pairing and structured linearization of such eigenproblems.

Work done in collaboration with Niloufer and Steve Mackey, Western Michigan University, Kalamazoo, MI 49008, USA.

Three numerical methods for the palindromic eigenvalue problem. **Christian Mehl** (TU Berlin, Germany) IC/MT2536/020

We discuss three numerical methods for the solution of the palindromic eigenvalue problem $Ax = \lambda A^T x$, where A is a complex matrix. Such eigenvalue problems occur, for example, in the vibration analysis of rail tracks. The first method is based on an idea that has been used by Laub for the solution of the Hamiltonian eigenvalue problem. The second method is a generalization of a non-symmetric Jacobi algorithm and the third method is a hybrid method that combines the best features of the first two methods, but also circumvents their failures.

This is joint work with D.S. Mackey, N. Mackey, and V. Mehrmann.

A numerical method for solving real Hamiltonian/skew-Hamiltonian eigenproblems. **Peter Benner** (TU Chemnitz, Germany) IC/MT4347/020

We discuss the computation of eigenvalues and deflating subspaces of real Hamiltonian/skew-Hamiltonian matrix pencils. Eigenproblems of this type arise in various application areas, in particular in linear-quadratic optimal control for descriptor systems and H_∞ optimization. In these applications, usually the stable deflating subspace, i.e., the subspace corresponding to the finite eigenvalues in the left half plane, is required.

The proposed algorithm is based on an embedding of the given matrix pencil in a Hamiltonian/skew-Hamiltonian pencil of double size for which a structured generalized Schur form can be computed. The method is efficient as it requires only about 2/3 of the computational effort the QZ algorithm would need to solve the original size generalized eigenproblem. We will also discuss the re-ordering of eigenvalues in detail as this is needed for obtaining the stable deflating subspaces required in the abovementioned applications.

IC/MP634/020: Preconditioners for sequences of linear systems.

Organiser: Philipp Birken (Universität Kassel, Germany)
Co-organiser: Jurjen Duintjer Tebbens (Academy of Sciences of the Czech Republic)

In many applications, not only one system of linear equations has to be solved, but a whole sequence of dozens, sometimes thousands of linear systems with different matrices and right hand sides obtained from the solution of previous systems.

Important examples are stiff differential equations or problems from optimization, where the appearing matrices are sparse and may be nonnormal. This minisymposium aims at discussing new techniques for solving these sequences of linear systems efficiently using preconditioned iterative methods. In particular, recently developed techniques that update preconditioners in contrast to freezing or recomputing them are considered.

The strategies to be addresses include approximate diagonal or triangular updates, recycled Krylov subspaces and Golub-Bartels types of updates.

An overview of efficient solution methods for sequences of linear systems. **Eric de Sturler** (Virginia Tech, USA) IC/MT3736/020

Many problems in science and engineering require the solution of a (long) sequence of linear systems. In order to solve such a sequence of systems efficiently, we want to reuse as much as possible previously calculated results. In addition to using the solutions of previous linear systems for an initial guess, we want to (1) *update* existing preconditioners to generate good preconditioners for subsequent problems at low cost, and (2) *recycle* search spaces from previous systems to improve the rate of convergence.

We will discuss several issues with respect to cost, effectiveness, and parallelism, and we will give an overview of current research in this area.

Updating incomplete factorizations for the solution of partial differential equations. **Jurjen Duintjer Tebbens** (Academy of Sciences of the Czech Republic), Daniele Bertaccini (Universita' di Roma "La Sapienza", Roma, Italy) IC/MT3473/020

The solution of algebraic linear systems of partial differential equations often requires the solution of sequences of large and sparse linear systems of the form

$$A_{\alpha_j} x = b, \qquad A_{\alpha_j} = A + \alpha_j E_j, \quad j = 0, \ldots, s, \quad \alpha_j \in \mathbf{C}, \qquad (1)$$

and E_j, $j = 0, \ldots, s$ are banded complex matrices.

These linear systems are often solved by iterative methods. However, without preconditioning these methods can converge very slowly and computing an incomplete factorization for each of the linear systems (1) can be costly and require memory space especially if s is large. On the other hand, reusing the same incomplete factorization strategy (e.g., computed for A) often leads to slow convergence. Clearly, there is a broad range of possibilities within these two extremes. We found a strategy for the update of an existing incomplete factorization preconditioner at a cost much lower than recomputing an incomplete factorization from scratch. Even if the resulting preconditioner can be expected to be less effective than a brand new one in terms of iteration count, the overall cost is, under suitable conditions, considerably reduced. The numerical solution of sequences of algebraic linear systems from the discretization of the real and complex Helmholtz equation and of

the diffusion equation illustrate the performance of the proposed approaches.

Sequences of linear systems as in (1) arise also in the numerical solution of the Helmholtz and of the Schrödinger equation; in large and sparse eigenvalues computation; in algorithms for nonlinear least squares and total least squares problems; in globalized quasi-Newton algorithms, etc.

Updating preconditioners for sequences of non-symmetric linear systems. **Philipp Birken** (Universität Kassel, Germany), Jurjen Duintjer Tebbens (Academy of Sciences of the Czech Republic), Andreas Meister (Universität Kassel, Germany), Miroslav Tůma (Czech Academy of Sciences, Czech Republic) IC/MT1578/020

The numerical solution of flows often leads to sequences of thousands of nonsymmetric linear systems with similar matrices and right hand sides. They are most currently solved with iterative methods preconditioned with ILU or other types of incomplete factorizations. The similarity of the matrices is exploited in praxis by recomputing the preconditioner not in every step, but periodically.

In this talk, a more sophisticated technique for nonsymmetric preconditioning is presented, where an incomplete LDU decomposition is updated in every step. The approach is algebraic and theoretically motivated. It generalizes diagonal updates previously introduced by Benzi and Bertaccini. Based on a reference LDU decomposition, the new preconditioner is computed via the difference between the current matrix and a reference matrix. This can be combined with a periodic recomputation of the reference preconditioner. It is demonstrated on several well-known testcases for the compressible Euler equations, that the new approach can reduce both CPU time and the total number of BiCGSTAB iterations.

Updating QR and LU factorizations in optimization. **Andreas Griewank** (Humboldt-Universität zu Berlin, Germany) IC/MT3498/020

In optimization algorithms approximating Jacobians and Hessians are frequently subject to low rank modifications due to changes in the active set or so called secant updates. In either case these corrections can be incorporated into QR or LU based factorizations at a cost that grows only linearly with the number of matrix entries. For square matrices dimension of n that means a cost of $O(n^2)$ rather than $O(n^3)$ for a complete refactorization. We review classical updating algorithms and observe that they may be unsatisfactory with regards to two criteria: data locality and asymptotic continuity. The first property is increasingly important for run time efficiency on modern computer architectures. The second properties means that the whole updating procedure reduces to the identity when the low rank meodifications tend to zero, which can be expected for secant updates.

IC/MP386/020: Preconditioning of symmetric indefinite systems in large-scale applications.

Organiser: Matthias Bollhöfer (TU Braunschweig, Germany)
Co-organiser: Olaf Schenk (Universität Basel, Switzerland)

One of the hardest challenges in the design of modern numerical solution methods is the design of robust and structure-preserving preconditioning techniques for highly symmetric indefinite linear systems, in particular those arising in PDE-constrained optimization or computational electronics based on Maxwell equations. Typically these problems require the computation of an approximate solution for systems which have up several million unknowns or larger due to their 3D spatial dimensions.
Continued advances in preconditioning techniques for symmetric indefinite systems and the ascendancy of modern software tools have in recent years motivated the use of these methods in large-scale applications.
In this minisymposium the first talk will address the computational challenges that arise in optimization with a focus on the preconditioning of symmetric indefinite linear systems, while the others will discuss theoretical and algorithmic advances for symmetric indefinite linear systems that arise from specific large-scale application problems such as PDE-constrained optimization and Maxwell problems. In particular the following aspects will be discussed:

- computational challenges that arise in large-scale optimization with focus on preconditioning of symmetric indefinite linear systems;
- Inertia-revealing preconditioning in large-scale nonconvex constrained optimization;
- augmentation techniques;
- implicit factorization preconditioners for KKT systems;
- KKT systems in optimal control of Magnetohydrodynamics;
- optimal control in large-scale constrained image construction;
- numerical challenges in industrial application problems arising from Maxwell equations;
- algebraic inverse-based preconditioning techniques for large-scale 2D/3D Helmholtz equations with high wave numbers.

Each topic is of interest in its own right. However, at the heart of each topic highly indefinite systems have to be solved numerically.

KKT systems arising in optimal control of magnetohydrodynamics. **Roland Griesse** (RICAM Linz, Austria) IC/MT1590/020

Magnetohydrodynamics (MHD) is a multi-physics phenomenon, dealing with the mutual interaction of electrically conducting fluids and magnetic fields. In particular, the magnetic fields interact with the electric currents in the fluid and exert a Lorentz force. This feature renders it so phenomenally attractive for exploitation especially in processes involving liquid metals, and in crystal growth.

The MHD forward or simulation problem has a saddle point structure, due to the constraints that the fluid velocity and current density be divergence free. The emphasis in this presentation will be on the large-scale linear systems arising in the simulation and optimal control of MHD, and their preconditioned iterative solution.

Preconditioners for distributed parameter-identification problems based on adaptive mesh refinement. **Eldad Haber** (Emory University, USA) IC/MT1781/020

In this talk we present an adaptive mesh discretization for distributed parameter identification problems. We then use this discretization in order to develop a highly efficient multigrid preconditioner for the systems which arise in the course of the constrained optimization algorithm.

Numerical challenges and industrial applications from frequency-domain simulations of Maxwell equations. **Stefan Reitzinger** (Computer Simulation Technology, Germany) IC/MT1288/020

In this talk we focus on the solution of Maxwell equations in frequency domain. Starting from a given 3D discretization of the full Maxwell equations, e.g. by the Finite Integration Technique (FIT), we end up with (depending on the boundary conditions and material properties) a sparse, large scale, indefinite, (non-)symmetric system matrix. This linear system has to be solved several times in a fast and robust way for different right hand sides. Because of the special properties of the Maxwell equations a "good" preconditioner has to be constructed very carefully. The construction of such a preconditioner based on algebraic multigrid principles is shown and additionally the numerical challenges are pointed out. Finally numerical studies from real life applications are presented.

Algebraic multilevel preconditioning for large-scale Helmholtz equations. **Matthias Bollhöfer** (TU Braunschweig, Germany) IC/MT1301/020

We discuss preconditioning methods for Helmholtz equation in two and three spatial dimensions with high wave number. In particular we present an algebraic multigrid algorithm that is based on three major ingredients, namely symmetric maximum weight matchings to increase the block diagonal dominance of the system, inverse-based pivoting to drive the coarsening process and finally filtering techniques to handle frequencies near zero eigenvalues. While the first two components can be considered as black-box approaches that can be widely used for preconditioning, the third component requires a more detailed adaption of the method to the underlying problem. I.e., in order to improve the coarsening process a pre-filtering method is applied prior to the inverse-pivoting approach.

IC/MP386/020: Preconditioning of symmetric indefinite systems in large-scale applications. #2

Co-organiser: Olaf Schenk (Universität Basel, Switzerland)

(For abstract, see session #1 above.)

Numerical solution of saddle-point systems. **Jörg Liesen** (TU Berlin, Germany) IC/MT4741/020

Linear systems in saddle point form arise in numerous applications throughout computational science and engineering. No single best solution method for such systems exists. Rather, methods are typically constructed for the specific problem at hand. The ubiquitous nature of saddle point systems has led to an overwhelming variety of methods, with new methods appearing in the literature constantly. The goal of this talk is to provide an overview of existing solution methods, and some guidance in this vast area of scientific computing.

Inertia-revealing preconditioning for large-scale non-convex constrained optimization. **Olaf Schenk** (Universität Basel, Switzerland) IC/MT1226/020

We propose an inertia revealing preconditioning approach for the solution of nonconvex contrained optimization problems. If interior methods with second-derivative information are used for these optimization problems, a linearized Karush-Kuhn-Tucker system of the optimality conditions has to be solved. The main issue addressed is how to ensure that the Hessian is positive definite in the null-space of the constraints while neither adversely affecting the convergence of Newton's method or incurring a significant computational overhead. In the nonconvex case, it is of interest to find out the inertia of the current iteration system so that the matrix may be modified *a posteriori* to obtain convergence to a minimum.

However, in order to not destroy the rapid convergence rate of the interior method, the modification has only be performed in the cases where the inertia is not correct and factorization methods[3,4] are very often used in order to compute the inertia information. In this work, we propose a new inertia revealing preconditioned Krylov iteration to solve the linearized Karush-Kuhn-Tucker system of optimality conditions. Our preconditioning approaches for the symmetric indefinite Karush-Kuhn-Tucker systems are based on maximum weighted matchings and algebraic multi-level incomplete LBL^T factorizations[1,2]. Finally, we present numerical results on several large-scale three-dimensional examples of PDE-constrained optimizations in the full space of states, control and adjoints variables with equality and non-equality constraints and test them with artificial as well as clinical data from biomedical cancer hyperthermia treatment planning.

This is joint work with Andreas Wächter (IBM Research) and Martin Weiser (ZIB, Berlin, Germany).

Augmentation preconditioners for saddle-point systems. **Chen Greif** (University of British Columbia, Canada) IC/MT1641/020

In this talk we provide an overview of augmentation preconditioners for saddle point systems of the form $[A\ B^T; B\ 0]$. Those preconditioners come in a few flavors. Defining W as a weight matrix, one basic form is block diagonal, with a weighted augmented matrix in the (1,1) block. The preconditioned matrix has the interesting property that the higher the nullity of the (1,1) block is, the faster a minimal residual Krylov solver (such as MINRES) converges. When the nullity of A is equal to the number of constraints, convergence (in the absence of roundoff errors) is expected to occur within two iterations. This preconditioning methodology fits certain situations in optimization quite well. For example, interior point solvers give rise to systems whose (1,1) block becomes increasingly ill-conditioned as the solution is approached.

Implicit factorizations for KKT systems. **Sue Dollar** (Rutherford Appleton Laboratory, UK) IC/MT1034/020

Each step of an interior point method for constrained optimization requires the solution of a system of equations which is symmetric, indefinite and takes the form

$$\begin{bmatrix} H & A^T \\ A & -C \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} c \\ d \end{bmatrix}.$$

Such a system is often called a KKT or saddle-point problem. As the problem size increases, the use of direct methods to solve this system may become prohibitively expensive and iterative methods become a viable alternative.

Dollar, Gould, Schilders and Wathen have recently proposed the use of implicitly defined constraint preconditioners when (approximately) solving KKT problems iteratively. These preconditioners only require the factorization of smaller systems and can be shown to give favourable Krylov subspace properties as well as allowing us to use a conjugate gradient-based iterative method. However, they often require a preprocessing step which carries out a symmetric permutation of the KKT problem. This permutation strongly relates to the problem of finding a nullspace basis of the linearized constraint space for the underlying optimization problem, but we'd also like to take additional characteristics of the Hessian into account when forming the permutation. We will discuss the desirable properties of such a permutation and how this might be achieved. Numerical experiments comparing several possible methods will be presented and it will shown that the more ill-conditioned the Hessian part of the KKT system is, the better the suggested preconditioners perform under suitable permutation choices.

This is joint work with Nick Gould, Wil Schilders and Andy Wathen.

IC/MP307/020: Numerical multilinear algebra: a new beginning.

Organiser: Pierre Comon (Université de Nice, France)
Co-organiser: Lieven De Lathauwer (CNRS-ETIS, France)
Co-organiser: Gene Golub (Stanford University, USA)
Co-organiser: Lek-Heng Lim (Stanford University, USA)

This minisymposium is on the development of numerical algorithms for multilinear algebra; a topic that is expected to have far-reaching applications in science and engineering, through both the creation of new scientific computing models and the analysis of data with nonlinear structures. The name *Numerical Multilinear Algebra* is not as yet in common usage. We broadly define this as the study and use of tensors/multilinear algebra, symmetric tensors/symmetric algebra, alternating tensors/exterior algebra, spinors/Clifford algebra in computational mathematics. A fundamental object of interest will be tensors. An order-k tensor may be either regarded as (1) a k-dimensional array of real/complex numbers on which algebraic operations generalizing analogous operations on matrices are defined, or (2) a linear combination of outer products of vectors. A matrix is then synonymous with a tensor of order 2. Special types of tensors such as symmetric and alternating tensors (arising from, say, cumulants and differential forms), Kronecker products of operators, are also of central importance. More specifically, this minisymposium will focus on numerical computations involving these multilinear objects, their surprising connections to questions regarding computational complexity and numerical stability, as well as the growing importance and increasing ubiquity of multilinearity in scientific and engineering applications.

The role of tensor rank in the complexity analysis of bilinear forms. **Dario Bini** (Universita' di Pisa, Italy) IC/MT3934/015

Three way-arrays (tensors) play an important role in the complexity analysis of sets S of bilinear form. In fact, the minimum number of (nonscalar) multiplications sufficient to compute S is given by the tensor rank of the three-way array $A = (a_{ijk})$ associated with S. Here, a tensor A has rank one if $A = (u_i \times v_j \times w_k)$ while it has rank at most $p > 1$ if there exist p rank-1 tensors T_i such that $A = T_1 + ... + T_p$.

Unlike matrices, there may exist sequences of tensors $\{A_p\}$ of given rank r which converge to a tensor of rank $r' > r$. This property has lead to the concept of border rank. While the tensor rank measures the complexity of computing sets of bilinear forms, the concept of border rank provides a measure of the complexity of approximating sets of bilinear forms.

In this talk, we provide an overview of known results concerning the complexity analysis of bilinear forms, discuss the role of multilinear algebra in this matter, present some extensions and list some open problems.

In particular, the concepts of tensor rank and border rank are revisited from a numerical point of view. Some criteria for giving lower bounds on the tensor rank and on the border rank of a given tensor are presented in terms of linear algebra tools, and their extensions to k-way arrays are discussed. Some examples are considered and a list of tensors whose (border) rank is still unknown is given.

Tensor computations for genomic signal processing. **Orly Alter** (University of Texas at Austin, USA) IC/MT3942/015

DNA microarrays make it possible to record the complete molecular biological signals that guide the progression of cellular processes on genomic scales. Biology and medicine today may be at a point similar to where physics was after the advent of the telescope [1]. The rapidly growing number of DNA microarray data sets holds the key to the discovery of previously unknown molecular biological principles, just as the astronomical tables compiled by Galileo and Brahe enabled accurate predictions of planetary motions and, later, the discovery of universal gravitation. Just as Kepler and Newton made these predictions and discoveries by using mathematical frameworks to describe trends in astronomical data, so future predictive power, discovery, and control in biology and medicine will come from the mathematical modeling of DNA microarray data, where the mathematical variables and operations represent biological reality: The variables, patterns uncovered in the data, might correlate with activities of cellular elements, such as regulators or transcription factors, that drive the measured signals. The operations, such as data classification and reconstruction in subspaces of selected patterns, might simulate experimental observation of the correlations and possibly also causal coordination of these activities. Such models were recently created from DNA microarray data by using the matrix computations of singular value decomposition (SVD) [2], generalized SVD (GSVD) [3] and pseudoinverse projection, and their ability to predict previously unknown biological as well as physical principles was demonstrated [4, 5]. I will now describe the first such data-driven models that were created from DNA microarray data by using tensor computations. First, I will describe the use of the matrix eigenvalue decomposition (EVD) and pseudoinverse projection and a tensor higher-order EVD in reconstructing the pathways that compose a cellular system from genome-scale nondirectional networks of correlations among the genes of the system [4]. Second, I will describe the use of a tensor higher-order SVD in integrating multiple datasets, corresponding to similar yet not identical biological studies of the same organism, and uncovering robust yet subtle differences among these datasets and corresponding studies. Third, I will describe the use of a tensor higher-order GSVD in comparing multiple datasets,

corresponding to similar biological studies of different organisms, and uncovering processes common or exclusive among these datasets and organisms.

Finite-element differential forms. **Douglas Arnold** (University of Minnesota, USA), Richard Falk (Rutgers University, USA), Ragnar Winther (Universitetet i Oslo, Norway) IC/MT3961/029

A differential form is a field which assigns to each point of a domain in Euclidean space or, more generally, a manifold, an alternating multilinear form on its tangent space. The exterior derivative operation, which maps differential forms of one order to differential forms of the next higher order, unifies the basic first order differential operators of calculus, and is a building block for a great variety of differential equations. When discretizing such differential equations by finite element methods, stable discretization depends on the development of spaces of finite element differential forms. As revealed recently through the finite element exterior calculus, for each order of differential form, there are two natural families of finite element subspaces associate to a simplicial triangulation. In the case of forms of order zero, which is are simply functions, these two families reduce to one, which is simply the well-known family of Lagrange finite element subspaces of the first-order Sobolev space. For forms of degree 1 and of degree $n-1$ (where n is the space dimension), we obtain two natural families of finite element subspaces of $H(\mathrm{curl})$ and $H(\mathrm{div})$, unifying many of the known mixed finite element spaces developed over the last decades. This talk will concern the construction of such spaces, their properties and inter-relationships, and the construction of natural geometric bases for them, which generalize the Bernstein basis for Lagrange elements.

Multilinear algebra in machine learning and signal processing. **Lek-Heng Lim** (Stanford University, USA), Pierre Comon (Université de Nice, France) IC/MT4000/029

We will discuss how numerical multilinear algebra arises in both discriminative and generative models in machine learning: tensors in multilinear regression models (generalization of vector space models), symmetric tensors in independent component analysis, and nonnegative tensors in graphical models (ie. Bayesian networks). We will also introduce a multilinear spectral theory and show how the eigenvalues of symmetric tensors may be used to obtain basic results in Spectral Hypergraph Theory.

We will also discuss how the problem of blind source separation in signal processing may be solved either with the decomposition a data tensor into a sum of rank-one terms in the presence of sufficient diversity, or with the help of high-order statistics, namely cumulant tensors. In the latter case, the decomposition of the data cumulant, a symmetric tensor, into a linear combination of rank-one symmetric tensors can be used to extract factors when physical diversity does not allow direct and efficient storage of the data.

Fast multilinear approximation: a new generation of numerical algorithms. **Eugene Tyrtyshnikov** (Russian Academy of Sciences, Moscow) IC/MT3243/015

Large-scale problems arising in numerical mathematics and data analysis certainly need new approaches. Anyway we should look for some low-parametric "numerically viable" structure hidden in the data, and we are interested in some general tools that can help. A new generation of numerical algorithms can be based on fast construction of low-parametric multilinear (tensor) approximations both for the original problem and for all stages of an iterative solver. We demonstrate the new approximation tools and first implementations of this idea that may lead even to sublinear complexity.

Tensor-product decomposition in computational physics. **Boris Khoromskij** (Max-Planck-Institut Leipzig, Germany) IC/MT3321/015

Modern methods of tensor-product decomposition allow an efficient data-sparse approximation to integral and more general nonlocal operators in higher dimensions (cf. [1] – [7]). Examples of such nonlocal mappings are classical volume potentials, solution operators of elliptic/parabolic BVPs, spectral projection operators associated with the matrix *sign* function for solving the Hartree-Fock equation in electronic structure calculations, collision integrals from the deterministic Boltzmann equation as well as the convolution integrals from the Ornstein-Zernike equation in molecular dynamics.

We discuss the approximation theory and numerical methods of structured low tensor-rank approximation to function-related tensors and operators based on the Tucker and canonical models. The asymptotic complexity of such approximations can be estimated by $O(\log^{pd} n + dn\log^q n)$ with $p \le 1$, where $N = n^d$ is the discrete problem size (hence, avoiding the "curse of dimensionality"). In particular, we consider applications to the classical Newton, Yukawa and Helmholtz potentials, to the multi-variate functions $\frac{1}{|x-y|^y}$ and $e^{-\alpha|x-y|^y}$ with $x, y \in \mathbb{R}^d$, as well as to the elliptic operator inverse. Numerical results will be addressed.

Separated representations and nonlinear approximations for fast algorithms in high dimensions. **Gregory Beylkin** (University of Colorado at Boulder, USA) IC/MT3914/015

As is well known, representing functions in an appropriate basis facilitates the solution of linear differential and integral equations. However, in nonlinear problems the role of bases is limited, since linear combinations of solutions are not solutions. Moreover, in high dimensions, representations via bases may have far too many components and, thus, their utility is questionable. As an alternative to bases we may use optimal or optimized representations of functions. In particular, we have been using separated representations as a tool for solving linear and nonlinear equations in high dimensions, with the optimization applied to reduce the number of terms in the approximation. We present examples of separated representations, nonlinear approximations, and the associated numerical algorithms.

Fast Newton-type methods for non-negative tensor approximation. **Inderjit Dhillon** (University of Texas at Austin, USA) IC/MT5040/015

Nonnegative Tensor Approximation is an effective decomposition technique that is useful in a wide variety of applications ranging from document analysis and image processing to bioinformatics. There are existing algorithms for nonnegative tensor approximation (NNTA), for example, Lee & Seung's multiplicative updates, alternating least squares, and certain gradient-descent based procedures. However, all these procedures suffer from slow convergence or numerical instabilities. In this talk, I will present improved algorithms for the NNTA problem, which overcome many computational deficiencies of existing methods. In particular, our methods use non-diagonal gradient scaling for faster convergence. These methods provide numerical results that are superior to both Lee & Seung's method as well to the alternating least squares (ALS) heuristic, which is known to work well in some situations but has no theoretical guarantees. I will present experimental results on both synthetic and real-world datasets to demonstrate the effectiveness of the new methods, in terms of better approximations as well as computational efficiency.

IC/MP271/020: Solution methods for sequences of linear systems and applications.

Organiser: Eric de Sturler (Virginia Tech, USA)

The simulation and optimization of systems arising in science and engineering often result in the solution of a sequence of linear systems where the matrix and possibly the right hand side(s) are changing. In some cases, such as crack propagation, thousands of systems must be solved. In many cases, the matrix changes slowly from one system to the next, and the changes often have special structure. For these applications, we can reduce the overall solution time drastically by exploiting the slowly changing nature of the matrices. For this reason, there is currently significant interest in developing linear solvers and preconditioners for sequences of linear systems. Several methods have been succesfully applied in applications ranging from tomography, the optimization of large structures, materials science, and stochastic finite elements for uncertainty quantification. This minisymposium aims to bring together both developers of solvers and researchers applying these solvers.

Solving sequences of linear systems: recent advances. **Eric de Sturler** (Virginia Tech, USA) IC/MT2722/020

We will start with an overview of methods that accelerate the solution of a sequence of linear systems by reusing information that is available from previous systems, and we discuss typical applications. After that we briefly discuss Krylov recycling for a sequence of symmetric linear systems and an application in topology optimization for optimal structures and advanced materials design. This is joint work with Glaucio Paulino and Shun Wang (UIUC).

Adaptive preconditioners for nonlinear systems of equations. **Daniel Loghin** (University of Birmingham, UK) IC/MT2767/020

The use of preconditioned Krylov methods is in many applications mandatory for computing efficiently the solution of large sparse nonlinear systems of equations. However, the available preconditioners are often sub-optimal due to the changing nature of the linearized operator. In this work we introduce and analyze an adaptive preconditioning technique based on the Krylov subspace information generated at previous steps in the nonlinear iteration. In particular, we use an adaptive technique suggested for restarted GMRES to enhance existing preconditioners with information available from previous Arnoldi factorizations computed in the course of the nonlinear iteration. Numerical tests drawn from the areas of optimization and nonlinear PDEs are used to illustrate the increased efficiency of our approach.

Physics-based preconditioners for solving PDEs on highly heterogeneous media. **Burak Aksoylu** (Louisiana State University, USA), Hector Klie (University of Texas at Austin, USA) IC/MT3335/020

Eigenvalues of smallest magnitude become a major bottleneck for iterative solvers especially when the underlying physical properties have severe contrasts. These contrasts are commonly found in many applications such as composite materials, geological rock properties and thermal and electrical conductivity. The main objective of this work is to construct a method as algebraic as possible that could efficiently exploit the connectivity of highly heterogeneous media in the solution of diffusion operators. We propose an algebraic way of separating binary-like systems according to a given threshold into high- and low-conductivity regimes of coefficient size $O(m)$ and $O(1)$, respectively where $m \gg 1$. The condition number of the linear system depends both on the mesh size Δx and the coefficient size m. For our purposes, we address only the m dependence since the condition number of the linear system is mainly governed by the high-conductivity subblock. Thus, the proposed strategy is inspired by capturing the relevant physics governing the problem. Based on the algebraic construction, a two-stage preconditioning strategy is developed as follows: (1) a first stage that comprises approximation to the components of the solution associated to small eigenvalues and, (2) a second stage that deals with the remaining solution components with a deflation strategy (if ever needed). The deflation strategies are based on computing near invariant subspaces corresponding to smallest and deflating them by the use of recycled Krylov subspace projections. Due to its algebraic nature, the proposed approach can support a wide range of realistic geometries (e.g., layered and channelized media). Numer-

ical examples show that the proposed class of physics-based preconditioners are more effective and robust compared to a class of Krylov-based deflation methods on highly heterogeneous media.

Subspace recycling for image-reconstruction applications. **Misha Kilmer** (Tufts University, USA), Eric de Sturler (Virginia Tech, USA) IC/MT2750/020

The need to solve a sequence of large-scale linear systems involving matrices whose characteristics vary slowly from one subsequent system to the next arises frequently in image reconstruction problems. In tomography applications (electrical impedance or diffuse optical tomography), for example, one often needs a nonlinear forward model in the form of a discretized partial differential equation (PDE) to describe the relationship between the desired quantity (e.g. a 3D image of the diffusion of light in tissue) and the measured data. To find the desired image requires the solution of a nonlinear optimization problem for the unknown voxel values in the image, which in turn requires the solution of multiple linear systems (the discretized PDEs) – one or more such systems in each iteration of the optimization algorithm. Even in applications where a linear forward model is used, sequences of systems can arise from time processing of data, or from sewing slices of information together to produce 3D images.

In this talk, we analyze matrix characteristics and techniques for reducing the computational complexity of the sequence of systems arising in tomography applications. In particular, we derive strategies for recycling Krylov subspace information that exploit properties of the application and the nonlinear optimization algorithm to significantly reduce the total number of iterations over all linear systems. Although we focus on a particular application, our approach is applicable generally to problems where sequences of linear systems must be solved. Examples illustrate the promise of our approach in reducing the overall computational complexity of nonlinear image reconstruction problems.

IC/MP271/020: Solution methods for sequences of linear systems and applications. #2

Organiser: Eric de Sturler (Virginia Tech, USA)

(For abstract, see session #1 above.)

Krylov-subspace recycling in stochastic finite-element computations. **Elisabeth Ullmann** (TU Bergakademie Freiberg, Germany), Oliver Ernst (TU Bergakademie Freiberg, Germany) IC/MT3324/020

A popular variant of the stochastic finite element method requires the solution of a large number of parametrized linear systems of equations. The associated coefficient matrices are linear combinations of a small number of finite element stiffness matrices resulting from coefficient functions which are eigenfunctions of a covariance operator. Since these parametrized matrices are closely related in this way, it is to be expected that Krylov subspace recycling techniques are able to efficiently reuse subspaces generated in the course of solving one equation for the approximation of other solutions.

In this talk we report our experience with Krylov subspace recycling techniques in combination with GCROT as well as a MINRES-like solver for families of Hermitian systems in a variety of stochastic finite element computations.

Analysis of Krylov-subspace recycling for sequences of linear systems. **Michael Parks** (Sandia National Laboratories, USA), Eric de Sturler (Virginia Tech, USA) IC/MT2763/020

We review a class of Krylov subspace methods for sequences of linear systems, which reduce the cost of solving the next system in the sequence by "recycling" information from previous systems. These methods have been successfully applied to sequences of linear systems arising from several different application areas. We analyze a particular method that recycles nearly invariant subspaces, and establish residual bounds that suggest a convergence rate similar to one obtained by removing select eigenvector components from the initial residual. Both symmetric and nonsymmetric problems are considered, and numerical experiments illustrating the effects of subspace recycling are presented.

Domain-decomposition preconditioned recycling GMRES algorithms for stochastic partial differential equations. **Xiao-Chuan Cai** (University of Colorado at Boulder, USA) IC/MT2746/020

In this talk, we discuss some parallel multilevel Schwarz-type domain decomposition preconditioned recycling Krylov subspace method for the numerical solution of some partial differential equations with stochastic uncertainties in the operator. Using a Karhunen-Loeve expansion and double orthogonal polynomials, we transform the stochastic problem into a large number of related, but uncoupled deterministic equations. To solve the systems efficiently, "recycling of computation" is the key. We report some interesting results obtained from a PETSc based parallel implementation of a recycling Krylov subspace method with a domain decomposition preconditioning. This is a joint work with C. Jin and C. Li.

Flexible GMRES with deflated restarting with application to a solution of the Helmholtz equation. **Xavier Pinel** (CERFACS, France), Luc Giraud (ENSEEIHT, France), Serge Gratton (CERFACS, France), Xavier Vasseur (CERFACS, France) IC/MT5029/020

In this talk we will describe a flexible Krylov subspace method that enables the preconditioner to change from one iteration to the next. It is referred to Flexible GMRES-DR due to its close ressemblance with the GMRES-DR method by R. Morgan in the way it recycles some spectral information at each restart. Numerical experiments for the solution of the Helmholtz equations using the multigrid scheme by Riyanti *et al.* as preconditioner will be reported.

This is joint work with L. Giraud (ENSEEIHT-IRIT), S. Gratton (CERFACS) and X. Vasseur (CERFACS).

IC/MP4145/020: Structured matrix algorithms: new methods.

Organiser: Olga Holtz (TU Berlin, Germany & UC Berkeley, USA)
Co-organiser: Plamen Koev (Massachusetts Institute of Technology, USA)
Co-organiser: James Demmel (UC Berkeley, USA)

Numerous applications in sciences and engineering, as well as in computational, applied and pure mathematics give rise to problems involving matrices with Toeplitz, Hankel, Vandermonde, Cauchy structures, along with many other patterns of structure. Standard mathematical software tools are mostly based on structure-ignoring methods, and therefore their use is often not appropriate for obtaining a satisfactory solution. Indeed, ignoring the structure can potentially increase the storage from $O(n)$ to $O(n^2)$ and increase the running time from $O(n)$ to $O(n^3)$, depending on the structure. Secondly, many structured matrices are extremely ill-conditioned, which means that all available standard methods may fail to produce even one correct digit in the computed solution. The only way to overcome these difficulties is to exploit the special structure of such matrices, and to design more efficient algorithms.

Fast linear algebra is stable. **James Demmel** (UC Berkeley, USA), Olga Holtz (TU Berlin, Germany & UC Berkeley, USA), Ioana Dumitriu (University of Washington, USA) IC/MT4023/020

We show that a large class of fast recursive matrix multiplication algorithms are stable in a normwise sense, and that if multiplication of $n \times n$ matrices can be done by any algorithm in $O(n^w)$ operations, then it can be done stably in $O(n^{w+e})$ operations for any $e > 0$. We extend this to show that many standard linear algebra operations, including LU and QR decomposition, linear equation solving, matrix inversion and determinant computation can also be done stably in $O(n^{w+e})$ operations.

Novel structured and unstructured preconditioners. **Victor Pan** (Lehman College, CUNY, USA) IC/MT1811/020

We propose a novel approach to preconditioning for solving linear systems of equations and some other fundamental matrix computations. Our preconditioners are readily available for quite a general class of ill conditioned matrices, with no preliminary information about the SVD, and can be chosen to preserve and exploit the structure of the input matrix. We describe various techniques for computing with our preconditioners, link them to the aggregation methods, and analyze them theoretically and experimentally.

Fast algorithms for polynomial Vandermonde matrices related to quasi-separable matrices. **Thomas Bella** (University of Connecticut, USA), Vadim Olshevsky (University of Connecticut, USA), Yuli Eidelman (Tel Aviv University, Israel), Israel Gohberg (Tel Aviv University, Israel) IC/MT3982/020

While general matrix algorithms are known to require $O(n^3)$ operations, the special structure of Vandermonde and Vandermonde-related matrices allows computational savings resulting in algorithms of only $O(n^2)$ operations for certain special classes. Specific classes that have already been considered are classical Vandermonde matrices, Chebyshev-Vandermonde matrices, three-term Vandermonde matrices, and Szegö-Vandermonde matrices. In each the known algorithms for inversion and for solving a linear system are of the lower $O(n^2)$ complexity. In this paper we consider the most general special class of quasiseparable-Hessenberg-Vandermone matrices that generalize all the above classes. We derive generalizations of the well-know Bjorck-Pereyra and Traub algorithms. The results of numerical experiments will be presented.

A quadratically-convergent method for solving certain Riccati equations based on structured matrix technology. **Dario Bini** (Universita' di Pisa, Italy) IC/MT3282/020

Structural and computational properties of Cauchy-like matrices are used for the design and analysis of algorithms for solving certain matrix Riccati equations encountered in transport theory. We provide an algorithm with complexity $O(n^2)$ ops per step having quadratic convergence, where n is the size of the matrix which solves the equation. The possibility of reducing the computational cost to $O(n)$ ops, up to polylog factors, is discussed.

IC/MP712/020: Structured matrix algorithms: complexity and stability.

Organiser: Olga Holtz (TU Berlin, Germany & UC Berkeley, USA)
Co-organiser: Plamen Koev (Massachusetts Institute of Technology, USA)
Co-organiser: James Demmel (UC Berkeley, USA)

Numerous applications in sciences and engineering, as well as in computational, applied and pure mathematics give rise to problems involving matrices with Toeplitz, Hankel, Vandermonde, Cauchy structures, along with many other patterns of structure. Standard mathematical software tools are mostly based on structure-ignoring methods, and therefore their use is often not appropriate for obtaining a satisfactory solution. Indeed, ignoring the structure can potentially increase the storage from $O(n)$ to $O(n^2)$ and increase the running time from $O(n)$ to $O(n^3)$, depending on the structure. Secondly, many structured matrices are extremely ill-conditioned, which means that all available standard methods may fail to produce even one correct digit in the computed solution. The only way to overcome these difficulties is to exploit the special structure of such matrices, and to design more efficient algorithms.

Over the last decade, numerically stable and fast methods have been developed for several classes of structured matrices (e.g., Cauchy, Vandermonde and generalized Vandermonde, matrices with low displacement rank). These new methods are being incorporated into software and libraries such as MATLAB and LAPACK. The proposed mini-symposium will bring together pure and applied mathematicians and software developers working on theoretical and computational problems involving structured matrices. This will create a unique opportunity to discuss advances and challenges in the area of structured matrix problems.

Structured matrices and reproducing-kernel spaces. **Harry Dym** (Weizmann Institute of Science, Israel) IC/MT2747/020

The purpose of this talk is to highlight the natural connections that exist between structured matrices and certain classes of reproducing kernel spaces. The link is made by interpreting the matrix as the Gram matrix of the space, which will be a finite dimensional Hilbert space if the given matrix is positive definite and a finite dimensional Krein space if the matrix is Hermitian and invertible. This connection has important implications in assorted problems of bitangential interpolation and factorization, as will be illustrated by examples. The talk will be expository.

Linear and multilinear structures in matrix approximation. **Eugene Tyrtyshnikov** (Russian Academy of Sciences, Moscow) IC/MT2628/020

Two important general types of structure in matrices include linear (like Toeplitz, etc.) and multilinear (low-rank matrices) structure. Previously both types have been studied separately. However, one can benefit a lot of a combination of both types of structure. Eventually it may lead to considerable reduction in number of representation parameters. Also, it opens up a new line for construction of preconditioners; i.e., *best circulant preconditioners* and far-reaching generalizations of the same approach.

Accurate algorithms for structured eigenvalue problems. **Froilán Dopico** (Universidad Carlos III de Madrid, Spain) IC/MT1981/020

In the last years an intense research effort has been done to identify special classes of matrices where very accurate spectral computations are possible and to develop efficient algorithms to perform these high accurate computations. At present many classes of symmetric matrices, definite or indefinite, deserving a high relative computation of their eigenvalues are known, but only two classes of nonsymmetric matrices have been identified. The main ideas behind these algorithms are: to choose for each class of matrices a set of parameters that determines its eigenvalues accurately, i.e., small relative perturbations of the parameters produce small relative changes in the eigenvalues, and to restrict some of the operations performed by the algorithms to accurate operations on the parameters. The purposes of this talk are: to present a unified overview on these algorithms and to present the most recent developments in this area.

Bidiagonal decomposition of totally positive Bernstein–Vandermonde matrices. **José-Javier Martínez** (Universidad de Alcala, Spain), Ana Marco (Universidad de Alcala, Spain) IC/MT3448/020

The class of Bernstein–Vandermonde matrices (a generalization of Vandermonde matrices arising when the monomial basis is replaced by the Bernstein basis) is considered. A convenient ordering of their rows makes these matrices strictly totally positive.

By using results related to total positivity and Neville elimination, an algorithm for computing the bidiagonal decomposition of a Bernstein-Vandermonde matrix is constructed. The use of explicit expressions for the determinants involved in the process serves to make the algorithm both fast and accurate.

One of the applications of our algorithm is the design of fast and accurate algorithms for solving Lagrange interpolation problems when using the Bernstein basis, an approach useful for the field of computer aided geometric design since it avoids the stability problems involved with basis transformations between the Bersntein and the monomial bases.

A different application consists of the use of the bidiagonal decomposition as an intermediate step of the computation of the eigenvalues and the singular value decomposition of a totally positive Bernstein-Vandermonde matrix.

Quasi-separable matrices and polynomials. **Vadim Olshevsky** (University of Connecticut, USA), Thomas Bella (University of Connecticut, USA), Israel Gohberg (Tel Aviv University, Israel), Yuli Eidelman (Tel Aviv University, Israel) IC/MT3964/020

Quasi-separable matrices are garnereing a lot of attention recently. Several results and algorithms for polynomials associated with quasiseparable matrices will be presented

Computing structured pseudospectra. **Daniel Kressner** (Umea University, Sweden) IC/MT3072/020

In the presence of high non-normality, the eigenvalues of a matrix or linear operator are not always helpful in understanding features of the underlying application. For example, the linear approximation of a dynamical system may have all eigenvalues far-off in the left half plane, even though the original system is unstable. In contrast, pseudospectra and related concepts (e.g., the pseudospectral radius) remain robust under uncertainties in the matrix and sometimes represent a more appropriate means to gain insights, e.g., on stability questions. In this talk, we consider structured pseudospectra, which arise if the uncertainties are known to preserve certain properties of the matrix. Computational aspects for the following classes of structured matrices are discussed: real matrices, skew-symmetric matrices, and Hermitian matrices. In all three cases, it turns out that computing one point of the structured pseudospectrum requires the solution of an eigenvalue minimization problem. Using appropriate reformulations and block Lanczos methods, it is shown how these minimization problems can be solved within a complexity that grows only quadratically with the matrix order and, hence, the computational cost is not much higher than for unstructured pseudospectra. Based on this work, a graphical user interface for computing structured pseudospectra, similar to Tom Wright's Eigtool, is being developed. This is joint work with Michael Karow.

Bayesian analysis of stability of structured matrix algorithms. **Daniela Calvetti** (Case Western Reserve University, USA) IC/MT3192/020

In this talk we analyse the stability of a few classes of structured matrix algorithms from the Bayesian perspective. In particular, we are interested in tracking how uncertainties in the initial data propagate to the computed solutions. Tools from Bayesian inference will be used to express uncertanty in terms of random variables. By using sampling methods we will present pointwise predictive envelopes for the output of the algorithms.

How does Matlab exploit matrix structure?. **Cleve Moler** (The MathWorks, Inc., USA) IC/MT1439/020

MATLAB does not have any specific "structured matrix" data type. This talk will examine how and where MATLAB does take advantage of various kinds of matrix structure – real versus complex, symmetry, positive definiteness, sparseness, bandedness, Toeplitz, Hankel, etc.

IC/MP672/020: Mathematical topics in matrix iterations.

Organiser: Marko Huhtanen (Teknillinen Korkeakoulu, Finland)
Co-organiser: Olavi Nevanlinna (Teknillinen Korkeakoulu, Finland)

This minisymposium deals with various mathematical problems related to iterative methods. Its partial purpose is to emphasize that advances in iterative methods do not result only from considering immediate applications. Even seemingly pure mathematical studies can lead to practical algorithms and approaches. In this type of research, tools and methods from many fields, such as complex and real analysis, operator and approximation theory, algebraic geometry, are needed.

GMRES and complex approximation theory. **Anne Greenbaum** (University of Washington, USA) IC/MT3579/020

Questions about the convergence of the GMRES algorithm for solving a linear system whose coefficient matrix is a Jordan block are related in an interesting way to certain problems in complex approximation theory. In [*The polynomial numerical hulls of Jordan blocks and related matrices*, Lin. Alg. Appl. 374 (2003), pp. 231-246] Faber, et. al. used an old result of Schur and Szegö about polynomial approximation to prove a new result about the polynomial numerical hull of degree $n-1$ for an n by n Jordan block and hence about the convergence of the GMRES algorithm applied to such a matrix. In [*GMRES convergence and the polynomial numerical hull for a Jordan block*, submitted to Lin. Alg. Appl.], Liesen and Tichý proved still more results about the convergence of the GMRES algorithm applied to a Jordan block and these, in turn, imply interesting new results about the behavior of polynomials in the complex plane. In this paper we show the connection between these seemingly different subjects and use the known results in each area to establish new results in the other.

Matrix nearness problems and iterative methods. **Marko Huhtanen** (Teknillinen Korkeakoulu, Finland) IC/MT2320/020

In this talk we consider measuring the deviation of $A \in \mathbb{C}^{n\times n}$ from unitarity in a more refined way by looking at

$$\min_{W\in\mathcal{U},F\in\mathcal{F}_k} ||A-F-W||,$$

for $k = 0,1,2,\ldots,n-1$. Here $\mathcal{U}$ denotes the set of unitary matrices and $\mathcal{F}_k$ matrices of rank k at most. Analogously to the way the singular values of A express how A is stratified away from zero, these numbers measure the deviation from unitarity in a more refined way.

Matrix iterative methods and potential theory. **Arno Kuijlaars** (Katholieke Universiteit Leuven, Belgium) IC/MT2099/020

Conjugate Gradients and the Lanczos method are basic iterative algorithms in numerical linear algebra. They belong to a class of Krylov subspace methods whose convergence properties can be described by a polynomial approximation problem. For large size matrices the approximation problem is analyzed with techniques from logarithmic potential theory. The theoretical results give good predictions for the convergence rates of the numerical methods.

Convergence of two-sided minimum residual iterations. **Olavi Nevanlinna** (Teknillinen Korkeakoulu, Finland) IC/MT2386/020

A two-sided minimum residual method was introduced[1] for problems of the form

$$(I+S)x = b$$

where fast operating with both S and S^{-1} are simultaneously available. In this talk we discuss the asymptotic convergence properties of such processes, suitably modifying the existing theory[2,3].

IC/MP347/020: Model reduction: structured and higher-order systems.

Organiser: Volker Mehrmann (TU Berlin, Germany)
Co-organiser: Roland Freund (UC Davis, USA)
Co-organiser: Zhaojun Bai (UC Davis, USA)

Model order reduction is currently one of the fundamental research areas in simulation and control of large-scale systems. Despite recent progress in the development of Krylov subspace methods, SVD-based methods, and POD methods, in most practical applications there is a discrepancy between fast and efficient methods to compute the reduced order model, preservation of physical properties of the system, like conservation laws, stability, passivity, or variational properties of the system.

There is a lot of research activity in this direction and it is the aim of this minisymposium to bring some of the key players in academia and industry together, to exchange the latest developments and to coordinate research activities. We focus on the preservation of structure, like that of symmetric or higher-order systems.

Numerical and semi-analytical structure-preserving model reduction for MEMS. **David Bindel** (Courant Institute, NYU, USA) IC/MT998/020

Micro-electro-mechanical systems (MEMS) devices usually involve interactions between different types of physics, which leads to meaningful structures in the models of these devices. These device models also frequently have subsystems which correspond to physical components about which the designer may have some intuition or prior knowledge. In this talk, we describe how the HiQLab simulator for resonant MEMS supports the construction of reduced models that preserve these structures. In particular, we describe how designers can describe, at a high level, subsystems that should be preserved in a Krylov subspace based reduced model. We also describe how HiQLab easily allows users to define global shape functions to augment or replace automatically-generated bases for the different substructures. We give examples of structure-preserving reduced models of high-frequency resonant MEMS which we have constructed as part of our study of damping in these devices.

Structure-preserving model reduction without using explicit projection. **Roland Freund** (UC Davis, USA) IC/MT1002/020

In recent years, there has been a lot of progress in Krylov subspace-based structure-preserving model reduction of large-scale linear dynamical systems. However, all existing methods first generate a basis matrix of the underlying Krylov subspace and then employ explicit projection using some suitable partitioning of the basis matrix to obtain a structure-preserving reduced-order model. There are two major problems with the use of such explicit projections. First, it requires the storage of the basis matrix, which becomes prohibitive in the case of truly large-scale linear dynamical systems. Second, the approximation properties of the resulting structure-preserving reduced-order models are far from optimal, and they show that the available degrees of freedom are not fully used. In this talk, we discuss Krylov subspace-based recduction techniques that do not require explicit projection and thus overcome the two major problems of projection methods.

Robust algorithms for parametric model order reduction. **Lihong Feng** (TU Chemnitz, PR China), Peter Benner (TU Chemnitz, Germany) IC/MT1140/020

In many engineering applications, physical models contain some parameters. Parametric systems can be used to describe for example geometry and/or material variations in the physical system. The goal of parametric model order reduction is to preserve the parameters in the reduced-order model. Using the parametric reduced-order model, one can do quick simulations with different values of the parameters with acceptable error.

This paper is based on the work by Daniel (2004), where a parametric model reduction method is proposed that resembles the AWE method for moment matching. Here, we will propose a robust numerical algorithm for realizing this method. We develop an algorithm which computes the moments of the parametric system implicitly rather than explicitly. The method can be interpreted as an Arnoldi-type method using a modified Gram–Schmidt implementation. In this way, good numerical stability properties can be expected as an orthonormal basis of the projection subspace (which is needed for computing accurate projectors for model order reduction) can be obtained. The proposed algorithm can deal with both single-input and multi-input linear parametric systems without limitation on the number of parameters in the system. Simulation results show that our algorithms are very promising for various engineering problems.

Solvability and numerical methods for quadratic model updating problems. **Wen-Wei Lin** (National Tsing Hua University, Taiwan) IC/MT1181/020

Model updating problem (MUP) concerns the modification of an existing but inaccurate analytical model with measured data. For models characterized by quadratic pencils, the measured data usually involve incomplete knowledge of natural frequencies, mode shaps, or other specral information. In conducting the updating we have two viewpoints in solving MUP.

(I) We incorporate the measured modal data in the analytical model producing an adjusted model on the mass, damping and stiffnes, that closely match the experimental modal data. The new methods are direct methods, which require $O(nk^2)$ flops, and employ sparse matrix technique when the analytical model is sparse. Here n is the size of coefficient matrices defining the analytical model and k is the number of measured eigenpairs.

(II) We match the desired measured data without tampering with the other part of unmeasured or unknown eigenstructure inherent in the original model. Such an updating, if possible, is said to be no spill-over, which is a challenging task in applications. WE provide a complete theory on when such an updating with no spill-over is possible.

IC/MP348/020: Model reduction in circuit simulation.

Organiser: Volker Mehrmann (TU Berlin, Germany)
Co-organiser: Zhaojun Bai (UC Davis, USA)
Co-organiser: Roland Freund (UC Davis, USA)

Model order reduction is currently one of the fundamental research areas in simulation and control of large-scale systems. Despite recent progress in the development of Krylov subspace methods, SVD-based methods, and POD methods, in most practical applications there is a discrepancy between fast and efficient methods to compute the reduced order model, preservation of physical properties of the system, like conservation laws, stability, passivity, or variational properties of the system.

There is a lot of research activity in this direction and it is the aim of this minisymposium to bring some of the key players in academia and industry together, to exchange the latest developments and to coordinate research activities. Model compiler, model order reduction and circuit simulation. **Richard Shi** (University of Washington, USA) IC/MT4180/020

This talk presents some latest progresses in model order reduction in circuit simulation. The specific emphasis is how a model compiler can be explored to analyze the underlying model structures and to direct efficient model order reduction.

Model order reduction for linear and nonlinear circuit simulation in nanoscale IC electronics. **Jan ter Maten** (NXP Semiconductors, The Netherlands), Arie Verhoeven (Technische Universiteit Eindhoven, The Netherlands), Thomas Voss (TU Delft, The Netherlands), Tamara Bechtold (NXP Semiconductors, The Netherlands), Wil Schilders (NXP Semiconductors, The Netherlands) IC/MT4188/020

Simulation for nanoelectronics requires that circuit equations are coupled to electromagnetics, semiconductor equations, and involves heat transfer. Model Order Reduction (MOR) is a means to speed up simulation of large systems. Existing MOR techniques have to be generalized to be applicable to the resulting system of (Partial) Differential-Algebraic Equations (DAEs, PDAES). Also nonlinearity and parameterization have to be taken into account. They are the key points to make MOR applicable in industrial simulation and occur in three related MOR topics: behavioural modeling (for use in system design), nonlinear and parameterized MOR (for use in the main simulations), and approximation methods using response surface techniques for robust design (for use in optimization). With respect to nonlinear systems, Proper Orthogonal Decomposition (POD) methods as well as extensions of the balanced truncation methods have recently been developed. We studied a generalization to DAEs based on least squares techniques. To reduce costs in evaluations Missing Point Estimation (MPE) was studied. The idea is to build a nonlinear reduced order model by projecting a part of the original equations onto the subspace spanned by the chosen set of basis functions. The technique has been successfully applied to partial differential equation (PDE) models and to reduce successfully a DAE model of an inverter chain model. The same DAE model was also considered to study Trajectory Piece-Wise Linear (TPWL), combined with "PoorMan's TBR" to reduce the locally linearized systems,

created along a typical time-domain trajectory of the original system, and compiling a weighted overall linearized system. The time points for updating the local Krylov basis are determined dynamically, based on error control. Combining the bases gives a POD-like approximation that allows to use linearized problems. We will also address several experiences with inclusion of parameters.

Approaches for model reduction of PDE-described systems. **Luca Daniel** (Massachusetts Institute of Technology, USA), Jacob White (Massachusetts Institute of Technology, USA) IC/MT4189/020

In applications as diverse as nano-photonics, bioMEMS, and aircraft design, system designers need approaches for automatically extracting dynamically-accurate and computationally-efficient models from partial-differential-equation (PDE) descriptions. The problem of extracting reduced models from arbitrary systems of PDE's is already extremely difficult, but system designers often need even more. Extracted models are most useful to designers when these models are parametric, and can therefore include the performance impact of manufacturing variations.

The standard approach to model reduction of PDE systems is to first discretize in space, and then convert the problem to a very large system of ordinary differential equations. If the resulting dynamical system is linear, then existing reduction techniques can be applied, albeit with modifications to address the infeasibility of directly factoring the resulting huge system matrices. For parameterized and nonlinear PDE's, the landscape of methods is far less well resolved, perhaps because the general problem is almost certainly intractable. There are some techniques that work well for very specific problems, but the limitations and the accuracy of these techniques have yet to be properly characterized. In this talk, the authors will give examples of several recently developed techniques, with the hope of inspiring a more concerted effort at better understanding the topic's theoretical underpinnings.

Parameterized interconnect macromodeling via a 2D Arnoldi process. **Yangfeng Su** (Fudan University, PR China), Zhaojun Bai (UC Davis, USA) IC/MT4192/020

A Krylov subspace projection method is proposed for the model-order reduction of large scale parameterized interconnect networks. The reduced system is constructed via a novel two-dimensional Arnoldi process such that it matches a prescribed number of the multiparameter moments. We call it the PIMTAP algorithm, which stands for Parameterized Interconnect Macromodeling via a Two-dimensional Arnoldi Process. The PIMTAP algorithm inherits the advantages of the existing multiparameter moment-matching methods, such as multivariable Taylor series method and the CORE method, and avoids the shortfalls of these methods. It is computationally stable and robust and preserves the structure and therefore the passivity of the original parameterized interconnect network.

IC/MP348/020: Model reduction in circuit simulation. #2

Model order reduction techniques from an application point-of-view in high-frequency simulations. **Stefan Reitzinger** (Computer Simulation Technology, Germany) IC/MT1290/020

In this talk we focus on model-order reduction techniques for two types of applications:
(a) Given a 3D discretization of the full Maxwell equations, e.g. by the Finite Integration Technique (FIT), the aim is to construct a much smaller model such that the S-parameters are well approximated up to a userdefined accuracy. A fast, robust and reliable solution exists via a band Lanczos method, where loss-free and weakly lossy structures can be calculated. However extensions to general lossy (e.g. lossy metal) and parameter dependent problems are required.
(b) Second, given a set of discrete S-parameters from, e.g. a Time Domain calculation. We would like to approximate the given S-parameters by a linear time invariant (LTI) system which is as small as possible, stable and passive in the whole frequency range. The difficulties for this application are (in general) the non-passive S-parameters and as a consequence the enforcement of passivity during the approximation process. In addition the set of S-parameters can be very large. Finally we would like to construct a SPICE list out of the LTI system which is as small as possible. The mentioned difficulties and possible solutions to them are discussed.

Work done in collaboration with M. Elger and P. Thoma, CST GmbH Darmstadt.

Passivity-preserving model reduction of differential-algebraic equations in circuit simulation . **Tatjana Stykel** (TU Berlin, Germany), Timo Reis (TU Berlin, Germany) IC/MT2001/020

We consider model order reduction of linear differential-algebraic equations arising in circuit simulation. We present an extension of the positive real and bounded real balanced truncation model reduction methods for such equations that are based on balancing the solutions of projected generalized Lur'e and Riccati matrix equations. Important properties of these methods are that stability and passivity are preserved in the reduced-order model and that there exist approximation error bounds. Numerical solution of the corresponding matrix equations using the special structure of circuit equations is also discussed.

Model order reduction techniques for linear systems with large numbers of terminals. **Peter Feldmann** (IBM T.J. Watson Research Center, USA) IC/MT4156/020

This contribution addresses the well-known difficulty of applying model order reduction (MOR) to linear circuits with a large number of input-output terminals. Traditional MOR techniques substitute the original large but sparse matrices used in the mathematical modeling of linear circuits by models that approximate the behavior of the circuit at its terminals, and use significantly smaller matrices.

Unfortunately these *small* MOR matrices become dense as the number of terminals increases, thus canceling the benefits of size reduction. The paper introduces a model reduction technique suitable for circuits with numerous terminals. The technique exploits the correlation that almost always exists be-

tween circuit responses at different terminals. The correlation is rendered explicit through an SVD-based algorithm and the result is a substantial sparsification of the MOR matrices. The proposed sparsification technique is applicable to a large class of problems encountered in the analysis and design of interconnect in VLSI circuits. Relevant examples are used to analyze and validate the method.

Parameterized and nonlinear MOR in the simulation of RF circuits . **Wil Schilders** (NXP Semiconductors, The Netherlands) IC/MT4179/020

IC design automation tools are indispensable for RF designers in the transition to the nano-scale era. These tools are needed to develop nano-scale designs of unprecedented complexity and performance and, in addition, enable the achievement of single-pass design success to avoid costly re-spins and the loss of market opportunities. Next generation designs will be challenged by an increased number of trouble spots, many of which negligible at lower frequencies but representing a significant limitation for future designs. These trouble spots will have to be accounted for during the design phase in order to avoid costly mishaps that can originate potential failures and additional design and silicon iterations, and must be addressed in future design automation tools.

The key to the avoidance of these trouble spots is the recognition that devices can no longer be treated in isolation. Complete RF blocks must be considered as one entity. Today, it is not possible to perform such analyses of complete RF blocks. The CHAMELEON RF project will deliver the methodologies and prototype tools to make this possible. The results will lead to design automation tools, in particular design verification tools, that can be used for comprehensive and highly accurate modeling of electromagnetic effects and other trouble spots in complete nano-scale RF blocks, thereby enabling designers to minimize turnaround time without compromising design quality and first-time-right requirements.

In the presentation, an overview will be given of the methods that are being developed within the CHAMELEON-RF project (see: http://www.chameleon-rf.org), and that will enable a fully coupled solution of RF blocks. The emphasis will be on model order reduction techniques for interconnected and parameterized systems, and some recent results on nonlinear MOR will also be presented.

IC/MP347/020: Model reduction: structured and higher-order systems. #2

Approximation and recovery of damped-wave operators. **Mark Embree** (Rice University, USA) IC/MT3098/020

Damped wave equations are canonical examples of second-order dynamical systems whose discretizations lead to structured first-order linear systems driven by non-symmetric matrices. In practice one may wish to determine material properties of a physical system based on measurements of vibration. In this talk, we shall describe a approximate technique for recovering spatially-dependent viscous damping from spectral data. As a natural consequence of this construction, one can estimate the number of eigenvalues that should be accurately captured by a reduced order model for this physical system. Numerical results will be compared to high-precision measurements taken from a monochord in our string laboratory. (This talk describes collaborative work with Steven J. Cox of Rice University.)

Advances in model reduction of structured dynamical systems. **Zhaojun Bai** (UC Davis, USA) IC/MT4088/020

In this talk, under a unified theory, we review our recent work on model reduction methods for structured dynamical systems. These include RLC/RCS interconnect circuits, even and palindromic systems in large scale optimal control and bilinear systems arising from bilinearization of nonlinear dynamical systems.

This is a joint work with Rencang Li, Volker Mehrmann, Daniel Skoogh, Yangfeng Su, Hongguo Xu and Xuan Zeng.

Nonlinear model order reduction methods for oscillatory systems and their applications. **Jaijeet Roychowdhury** (University of Minnesota, USA) IC/MT4089/020

The lack of fast yet accurate oscillator and PLL simulation methods has constituted a serious bottleneck in mixed-signal, RF and digital design flows. We will describe methods that, given differential equations for any oscillator (ie, equivalent to, eg, a SPICE-level circuit), will extract a simple nonlinear phase macromodel. We will show how such nonlinear phase macromodels are capable of capturing a variety of important effects, including jitter and phase noise, injection locking, PLL lock and capture phenomena, cycle slipping, etc., while being faster by several orders of magnitude than SPICE-level simulation. Time permitting, we will also show how this nonlinear phase macromodel, when applied to large systems of networked biochemical and and nanoelectronic oscillators, correctly predicts spontaneous pattern formation and edge detection.

Entropy-based empirical relations between original and reduced state variables. **Patricia Astrid** (Shell Global Solutions International B.V, The Netherlands) IC/MT4168/020

In projection-based model reduction methods, the reduced basis which approximates the original dynamics is derived from the main dynamical features inferred from the collected state variable evolutions, controllability, or observability Gramians. However, the relations between original and reduced state variables are not explicitly available since all original state variables are entangled in the reduced basis. This paper presents an empirical method developed from the Shannon Entropy concept which identifies the individual relations between the original and reduced state variables. The empirical relations are applied in the closed loop control design of a spatio-temporal model reduced by the POD method. The incorporation of the empirical relations in the closed loop design results in a more effective closed loop performance.

IC/MP353/020: Numerical linear algebra in image processing.

Organiser: James Nagy (Emory University, USA)
Co-organiser: Misha Kilmer (Tufts University, USA)

Digital images are used to analyze objects in a variety of applications, such as star clusters in astronomy, molecules in biology, and tumors in medicine. Often the process used to obtain the image cannot be easily repeated, and the collected data must be used to reconstruct, restore or enhance the image. These processes often require the solution and/or analysis of challenging computational linear algebra problems. For example, special techniques must be used for very large linear systems that arise in three dimensional imaging applications, as well as for applications that require solution of constrained optimization problems. Often matrix approximations and fast algorithms for structured matrices must be employed. Due to advances in technology, the development of new imaging devices, and the desire to obtain images with ever higher resolution, research in these areas is extremely active. The speakers in this minisymposium will report on recent developments in numerical linear algebra models and algorithms that have been developed for tackling challenging problems in image processing.

Super-resolution methods for multi-lenslet iris-imaging system. **Victor Pauca** (Wake Forest University, USA), Todd Torgersen (Wake Forest University, USA) IC/MT3236/020

Multi-lenslet imaging systems offer a number of significant advantages over standard single-lens camera systems, including thin form-factor and wide angle of view. By using appropriate lenslet spacing relative to the detector pixel pitch, the resulting ensemble of images implicitly contains subject information at higher spatial frequencies than those present in a single image. Additionally, a multi-lenslet approach enables the use of observational diversity, including phase, polarization, neutral density, and wavelength diversities. For example, post-processing multiple observations taken with differing neutral density filters can yield an image having an extended dynamic range. As a part of the DTO-funded PERIODIC project, our research group has developed several multi-lens camera prototypes for the investigation of such diversities. In this talk, we present recent results obtained by our research group on superresolution of iris imagery using novel multi-lens imaging systems and iterative methods for (sequential and joint) registration and reconstruction. More specifically, we compute high-resolution reconstructed images from ensembles of low-resolution images containing sub-pixel level displacement diversity. Quality of the reconstructed images is measured in terms of biometric identification for iris recognition, by computing the Hamming distance between the Daugman iris code of a conventional reference iris image, and the iris code of a corresponding reconstructed image. We present numerical results concerning the reconstruction of actual iris data obtained with our camera prototypes.

Multilevel regularization for image deblurring problems. **Marco Donatelli** (Università degli Studi dell'Insubria Como, Italy) IC/MT1659/020

We consider the de-blurring problem of noisy and blurred signals/images in the case of space invariant point spread functions. The use of appropriate boundary conditions leads to linear systems with structured coefficient matrices related to space invariant operators like Toeplitz, circulants, trigonometric matrix algebras etc. We combine an algebraic multigrid (which is designed ad hoc for structured matrices) with the low-pass projectors typical of the classical geometrical multigrid employed in a PDEs context. Thus, using an appropriate smoother, we obtain an iterative regularizing method based on: projection in a subspace where it is easier to distinguish between the signal and the noise and then application of an iterative regularizing method in the projected subspace. Therefore any iterative regularizing method can be used as smoother in our multigrid algorithm. The projector is chosen in order to maintain the same algebraic structure at each recursion level and having a low-pass filter property, which is very useful in order to reduce the noise effects. In this way, we obtain a better restored image with a flatter restoration error curve and also in less time than the auxiliary method used as smoother. As direct consequence the choice of the exact iteration where to stop is less critical than in other regularizing iterative methods.

Work done in collaboration with S. Serra-Capizzano.

Multilevel approaches for the total least-squares method in deblurring problems. **Malena Español** (Tufts University, USA), Misha Kilmer (Tufts University, USA), Dianne Oleary (University of Maryland, USA) IC/MT2569/020

In some image deblurring applications, complete knowledge of the blurring operator is unavailable. Thus, the inverse problem of recovering the deblurred image in the presence of noise is complicated by the need to model the uncertainty in the blurring operator, adding to the computational complexity of the inversion. Regularized total least squares approaches have been presented in the literature which require the minimization of a functional with respect to the unknown perturbation in the blurring operator, the residual, and the desired image. However, much of the work to date has required the perturbation operator to have special structure (e.g. sparsity structure or Toeplitz type structure) in order to make the minimization problem more computationally tractable. We present a multilevel approach to the regularized total least squares problem which allows us to remove this operator restriction and still has the advantage of computational speed. Examples illustrate the potential effectiveness of our approach.

Cascadic multilevel methods for ill-posed problems. **Lothar Reichel** (Kent State University, USA) IC/MT3616/020

Multilevel methods are popular for the solution of well-posed problems, such as certain boundary value problems for partial differential equations and Fredholm integral equations of the second kind. However, little is known about the behavior of multilevel methods when applied to the solution of linear ill-posed problems, such as Fredholm integral equations of the first kind, with a right-hand side that is contaminated by error. We discuss properties of cascadic multilevel methods with a conjugate gradient-type method as basic iterative scheme. In particular, we consider applications to image deblurring and denoising using edge-preserving prolongation operators based on partial differential equations defined by Perona-Malik and total variation-type models. The talk presents joint work with Serena Morigi, Fiorella Sgallari, and Andriy Shyshkov.

IC/MP353/020: Numerical linear algebra in image processing. #2

Antireflective deblurring. **Martin Hanke** (Universität Mainz, Germany) IC/MT1207/020

We consider the numerical solution of selfadjoint deblurring problems on bounded intervals. For these problems it has recently been shown that appropriate modelling of the solution near the boundary of the interval may significantly improve the numerical reconstructions. Among the alternatives the so-called antireflective boundary condition appears to be the best known choice. Here we develop an appropriate, i.e., stable and efficient implementation of this model in two steps, namely by (i) transforming the problem to homogeneous boundary values, and (ii) using the fast sine transform to solve the transformed problem. This approach allows to incorporate regularization in a very straightforward way. Numerical reconstructions are superior to those obtained with the reblurring method of Donatelli and Serra-Capizzano.

Wave-front estimation for adaptive optics systems on ground-based telescopes. **Johnathan Bardsley** (University of Montana, USA) IC/MT1818/020

The earth's atmosphere is not a perfect media through which to view objects in outer-space; turbulence in the atmospheric temperature distribution results in refractive index variations that interfere with the propagation of light. As a result, wavefronts are non-planar when they reach the ground. The deviation from planarity of a wavefront is known as phase error, and it is phase error that causes the refractive blurring of images. Adaptive optics systems seek to remove phase error from incoming wavefronts. In ground-based astronomy, an estimate of the phase error in a wavefront is typically obtained from wavefront gradient measurements collected by a Shack-Hartmann sensor. The estimate is then used to create a counter wavefront, e.g. using a deformable mirror, which (approximately) removes the phase error from the incoming wavefronts. The problem of reconstructing the phase error from Shack-Hartmann gradient measurements requires the solution of a large linear system. This system is defined by the configuration of the Shack-Hartmann sensor. We derive its form and then present several effective computational methods Ű both old and new Ű for its solution.

A modified GCV method for Lanczos hybrid regularization. **Julianne Chung** (Emory University, USA), James Nagy (Emory University, USA) IC/MT1338/020

Lanczos hybrid regularization methods have been proposed as effective approaches to solve large-scale ill-posed inverse problems. Regularization parameters must be chosen at each iteration. In this talk, we describe a modified generalized cross validation scheme for this purpose. Some theoretical results are given, and numerical experiments show that the modified GCV method is effective at choosing regularization parameters.

A parameter-choice method that exploits residual information. **Per Christian Hansen** (Danmarks Tekniske Universitet, Denmark), Misha Kilmer (Tufts University, USA) IC/MT3711/020

Most algorithms for choosing the regularization parameter in a discrete ill-posed problem are based on the norm of the residual vector. We present a new approach, where we seek to use all the information available in the residual vector. We present important relations between the residual components and the amount of information that is available in the noisy data, and we show how to use statistical tools and fast Fourier transforms to extract this information efficiently. This approach leads to a computationally inexpensive parameter-choice rule based on the normalized cumulativeperiodogram, which is particularly suited for large-scale problems.

IC/MP131/020: Developments in algebraic multigrid methods for real-world applications.

Organiser: Luke Olson (Univ. of Illinois at Urbana-Champaign, USA)
Co-organiser: Scott MacLachlan (TU Delft, The Netherlands)

As the demand for more complex computational simulations continues to grow, so do the challenges imposed on the underlying numerical algorithms. This minisymposium highlights recent progress in the numerical solution of the large, sparse linear systems that arise in simulation of real-world applications. In particular, recent advances in algebraic multigrid (AMG) methods are considered in four areas of interest to the practitioner: theoretical analysis, parallel robustness, feasibility for advanced discretizations, and practical industrial application.

Algebraic multigrid has been established as an effective solution technique for a wide variety of problems. Improving its viability as an optimal or near-optimal black-box solver (yielding $\mathcal{O}(n)$ growth in complexity for $n \times n$ systems of equations) in real-world simulations requires a closer look at several challenges posed by traditional approaches. Simulations of complex, three-dimensional, real-world applications provide a motivational base for continued research. The challenges of accurately modelling the underlying physics coupled with the practical demands of simulation provide unique challenges to AMG. Simulation in high-performance environments, for example, is a common roadblock and both the AMG setup and solve phases are impacted in a parallel setting. Further, while standard finite-element discretizations are amenable to multigrid iteration, less conventional paradigms, such as high-order discontinuous spectral methods, offer significant advantages in terms of accuracy per degree of freedom. Better understanding of these challenges, both computationally and theoretically, provide a solid base for the practitioner.

The principle goal of this minisymposium is to outline these challenges and the associated progress towards more robust, efficient, and well-understood algebraic multigrid solution methods for real-world applications.

Practical aspects of theoretical bounds on algebraic multigrid. **Scott MacLachlan** (TU Delft, The Netherlands), Luke Olson (Univ. of Illinois at Urbana-Champaign, USA) IC/MT3760/020

Algebraic multigrid (AMG) techniques offer optimal performance as solvers or as preconditioners for many large-scale linear systems that arise in modern applications. Many of these applications, however, exhibit strongly heterogeneous characteristics that preclude analysis using classical techniques such as Fourier analysis. In this talk, we introduce AMG and discuss the challenges of deriving good theoretical bounds on its performance. In particular, we consider challenges in making practical choices in the algorithmic components based on theoretical analysis.

Theoretical bounds on AMG performance come with many different conditions and assumptions, reflecting AMG's many variants and options. For the practitioner, however, it is desirable to have a simple sharp bound that accurately reflects the choices made in constructing the AMG grid and operator hierarchies. The questions of sharpness and computability of existing bounds on AMG convergence are thus considered. The role in which recent advances in adaptive AMG and compatible relaxation play in these bounds is also discussed. Despite these and other advances, the challenge of deriving useful bounds for complex applications subject to limitations of computer architectures remains distant; our viewpoint suggests possibilities for research to achieve this goal.

Algebraic multigrid for high-order discretizations. **Luke Olson** (Univ. of Illinois at Urbana-Champaign, USA) IC/MT3359/020

The use of high-order spectral and finite elements in the numerical approximation to partial differential equations continues to grow in popularity. In many situations, the accuracy per degree of freedom when using high-order elements surpasses the low-order approach. The total computational cost, however, requires a deeper investigation of the complexity in the full simulation tool chain. In this talk, we focus on a common and nontrivial component of the process: solution of the associated algebraic system of equations. In particular, we highlight an algebraic-based multigrid (AMG) preconditioner for nodal elements on rectangular meshes as well as unstructured simplex meshes in both two and three dimensions [1,2].

For simplex meshes we consider high-order nodal spectral elements based on the electrostatic and Fekete distributions and tensoral GLL nodes in the case of rectangular grids. A low-order finite element preconditioner over a local tessellation of the element is constructed. We detail the use of AMG in this context for elliptic problems and investigate the performance. Notably, by utilizing the low-order AMG preconditioner, the solution process maintains optimal complexity for moderately high-order elements ($p = 12$ in 2D and $p = 10$ in 3D). Furthermore, with a modified AMG preconditioner, we are able to achieve similar performance for nonconforming discretizations such as the local discontinuous Galerkin method.

Markov chains and web ranking: a multilevel adaptive aggregation method. **Hans De Sterck** (University of Waterloo, Canada) IC/MT1993/020

Google's PageRank method for ranking web pages models how a *random surfer* follows links between web pages in a random fashion. The stationary probability vector of the resulting Markov chain provides a ranking of all the pages in the network. Calculating this stationary probability vector is a very large problem: Google now indexes more than 25 billion internet web pages. We present a multilevel adaptive aggregation method for the linear algebra problem of calculating the stationary probability vector of a Markov chain. The method described is a variant of adaptive algebraic multigrid methods for sparse linear systems, and is also related to existing aggregation methods for Markov chains. We apply our multilevel method to a set of stochastic matrices that provide models for web page ranking. These numerical tests serve to illustrate for which types of stochastic matrices our multilevel adaptive method may provide significant speedup compared to standard iterative methods. The tests also provide some insight into why the PageRank model is a successful model for determining a ranking of web pages.

On the use of algebraic multigrid methods in surgery simulations of complex geometries like the human head. **Jens Schmidt** (NEC Europe, Germany) IC/MT3492/020

We are dealing with the simulation of maxillo-facial surgeries, especially with distraction osteogenesis. During this treatment the surgeon cuts free the patient's upper jaw (maxilla), which is subsequently relocated into a new position in the course of several weeks, using a distraction device.The presented simulation toolchain is set up to predict the displacements of the facial tissues during and after the pulling process and is based on individual CT images of the patient's head before treatment. Its purpose is to support the surgeon in optimizing the treatment plan and avoiding additional post operative plastic surgeries.The input data for the simulation toolchain is generated by adding the suggested cuts, the geometry of the distraction device and the suggested forces to the CT data of the patient's head. From these data we generate a Finite Element mesh of the head and perform a Finite Element analysis of the distraction process.

In order to achieve sufficient accuracy we have to resolve most of the geometrical features of the human head, which leads to a large number of unknowns, typically several million. In addition the computational costs are significantly increased by the size of the displacements and the visco-elastic behaviour of the materials, which can only be properly approximated by non-linear modeling. The image processing, the meshing and the analysis of the model are run via a grid service on an HPC resource. Focusing on the efficiency of the simulation, the linear solvers used to solve the arising systems of equations play the most crucial role. In our case standard iterative solvers like Krylov methods or ILU methods fail, as we will show in our presentation. Therefore we will focus on the use of Multigrid solvers.

But the complex geometry of the human head in combination with large jumps of the material parameters (Young's modulus jumps about 5 orders of magnitude between bone and soft tissues) prevents standard multigrid approaches from converging at a sufficient rate. In theory convergence can be dramatically improved by computing the *near null space* of the systems, consisting of quasi-rigid body modes, and treating it separately. We will show the limitations of this approach for highly complex geometries, like the human head.In our presentation we will demonstrate the performance of three AMG-based solvers we have found to work on our problems: BoomerAMG from LLNL's hypre package [1], ML from Sandia's Trilinos package [2] (based on smoothed aggregation) and the PARDISO package [3] from the University of Basel, Switzerland (based on algebraic multilevel incomplete LDL^T factorizations). We will show the results of our intensive parameter studies and discuss the extensibility of our performance results for elasto-mechanical Finite Element simulations in general.

IC/MP268/020: Matrix functions: methods and applications.

Organiser: Valeria Simoncini (Dipartimento di Matematica, Universita' di Bologna, Italy)
Co-organiser: Andreas Frommer (Bergische Universität Wuppertal, Germany)

The approximation of matrix functions has received significant attention during the past few years, resulting in great advances in the numerical treatment as well as in the use of matrix functions in applied sciences. The aim of this minisymposium is to gather leading researchers in the subject to present recent developments in the study of numerical methods for the approximation and use of matrix functions.

Effects of non-normality on the behavior of matrix functions. **Anne Greenbaum** (University of Washington, USA) IC/MT3578/020

The behavior (in 2-norm) of a function of a normal matrix A, such as $\exp(A)$ or A^k, is determined by the eigenvalues of A. This is not so for nonnormal matrices, and we discuss other properties of such matrices that one might look at in order to estimate $\|f(A)\|$ for various functions f. Possibilities include the field of values, pseudospectra, polynomial numerical hulls, matrices that are similar to A via a well-conditioned similarity transformation, and more diagonally dominant matrices that are unitarily similar to A. We discuss the theory and application of several of these ideas.

Restarted Krylov-subspace approximation of matrix functions. **Stefan Güttel** (TU Bergakademie Freiberg, Germany), Oliver Ernst (TU Bergakademie Freiberg, Germany), Michael Eiermann (TU Bergakademie Freiberg, Germany) IC/MT3067/020

Approximating the product of a function $f(A)$ of a matrix A with a vector b is a key task in many scientific computing applications. When the matrix A arises from the discretization of a differential or integral operator, methods based on the direct factorization become too expensive and Krylov subspace projection methods become attractive. One shortcoming of this methodology, however, is its large storage requirements when a large number of iteration steps are required for a sufficient approximation.

Recently, we proposed a technique for restarting a Krylov subspace calculation resulting in fixed storage requirements which can be specified *a priori*. In this talk we present an enhancement of this method which reduces the amount of computation in the subspace calculation based on an updated Schur factorization. We compare the resulting algorithm with the previous one for several numerical examples.

Gaussian quadrature rules for second-order finite-difference schemes. **Vladimir Druskin** (Schlumberger Ltd., USA), Leonid Knizhnerman (Central Geophysical Expedition, Russian Federation), Liliana Borcea (Rice University, USA), Fernando Guevara Vasquez (Stanford University, USA) IC/MT2037/020

To evaluate $f(A)b$, Krylov subspace methods approximate A by small structured matrices T, in particular, by a tri-diagonal matrix, that matches some moments of the spectral measure of A. One can consider A as a one-dimensional second order differential operator and T as the matrix of the three-point (second order) finite-difference (FD) operator with a specially chosen grid [Druskin, Knizhnerman, SINUM, **37**, 2, 2000, 403-426], hence the name FD Gaussian rules (FDGR). The grids generated by the FDGR are also called optimal for shorthand. The most remarkable property of the optimal grids is exponential convergence of the transfer (also known as spectral or Weyl) function of the FD operator at the boundary of the domain, but globally the scheme converges with first or second order. With the help of tensor-product grids and domain decomposition this property can be transformed to exponential superconvergence of multidimensional second order FD approximations at targeted points or manifolds. Another important property of the optimal grids is their weak dependence on distribution of coefficients for certain classes of PDEs. We discuss applications of the FDGR to the solution of forward and inverse PDE problems arising in oil exploration and medical imaging.

An acceleration technique for the numerical solution of certain matrix equations. **Beatrice Meini** (Università di Pisa, Italy) IC/MT1264/020

Consider the matrix function:

$$\mathcal{R}(X) = XCX - XD - AX + B, \qquad (1)$$

where A, B, C, D are real matrices of sizes $m \times m, m \times n, n \times m, n \times n$, respectively, such that

$$M = \begin{bmatrix} D & -C \\ -B & A \end{bmatrix}$$

is an irreducible singular M-matrix, and X is real of size $m \times n$. The matrix function $\mathcal{R}(X)$ has applications in transport theory and Markov models. The interest is the computation of the minimal nonnegative solution X_+ of the equation $\mathcal{R}(X) = 0$. The latter equation is a nonsymmetric algebraic Riccati equation (NARE).

We introduce a new approach to treat the singularity of M based on a shift technique. The shift consists in performing a rank-one correction of the matrix M which moves one zero eigenvalue to a suitable nonzero real number. We construct a new matrix function $\tilde{\mathcal{R}}(X)$ which defines a NARE associated with the shifted M, which has the same solution X_+ of the original one, while the coefficients of the new Riccati equation form a nonsingular matrix if 0 is a simple eigenvalue of M.

The performances of various algorithms applied to the original and to the shifted Riccati equations are analyzed. In particular, it is proved that the convergence of the SDA (Structure Preserving Doubling) algorithm is accelerated when it is applied to the shifted Riccati equation.

IC/MP268/020: Matrix functions: methods and applications. #2

Computing functions of matrices via quadrature and conformal maps. **Lloyd Trefethen** (University of Oxford, UK) IC/MT2669/020

One of the most powerful and flexible tools for computing $f(A)$, where A is a matrix or operator, is a Cauchy integral. By using suitable variable transformations related to the IMT and DE methods of Mori and others, these algorithms can be made very fast indeed. A crucial part of their analysis is interpreting the transformations as conformal maps.

We will describe recent progress in this area, partly joint work with Nick Higham.

Recent advances in the implementation of exponential integrators. **Marlis Hochbruck** (Universität Düsseldorf, Germany) IC/MT3774/020

The efficiency of exponential time integration schemes strongly depends on the algorithms used for evaluating or approximating the product of a matrix function an a vector.

In this talk we will discuss various options for computing $f(A)b$ which may be incorporated into existing algorithms:

1. We consider the approximation of the product of a matrix function with a set of vectors, $f(A)b_i$, $i = 1,\ldots,s$, using Krylov subspace methods. We assume that A is a constant matrix and that the vectors b_i correspond to the evaluation of a smooth function at certain quadrature nodes. This problem arises in the implementation of exponential integrators, in which case f is related to the exponential function. We propose a projection technique and analyse its properties. Our analysis gives rise to a new practical stopping criterion for the iteration. Moreover, we present numerical examples which show a significant gain in computational time compared to a naive implementation, where a new Krylov basis is computed for each vector b_i.
2. For solving linear systems of equations with subspace iterations, restarts are a well established tool. Recently, Eiermann and Ernst showed how restarts can be incorporated into the evaluation of $f(A)b$. We will give an alternative derivation which might help to understand the convergence behavior of these approximations.

This is joint work with Jörg Niehoff.

Function of structured matrices in geometric integration of ODEs. **Luciano Lopez** (Universita' di Bari, Italy) IC/MT1472/020

In this talk we present methods for evaluating the exponential function at structured matrices like skew-symmetric and/or Hamiltomian ones. These results are essentially motived by the study of geometric integrators for solving ODEs evolving on matrix groups like the orthogonal or symplectic group, where the numerical solution is required to lie on the same matrix group of the theoretical solution. By exploiting the particular form of these structured matrices we may derive effective methods which preserve the exponential function on the associated matrix group. The possibility to use Krylov subspaces methods in the context of geometric integrator is also investigated.

Numerical methods for the QCD overlap operator: hybrid Monte-Carlo with overlap fermions. **Thomas Lippert** (Forschungszentrum Jülich, Germany), Nigel Cundy (Universität Regensburg, Germany), Andreas Frommer (Bergische Universität Wuppertal, Germany), Stefan Krieg (Forschungszentrum Jülich, Germany) IC/MT3754/020

The use of chiral (e.g., overlap) fermions offers an intriguing possibility for the simulation of QCD at small masses. The computational costs of calculating the sign of the Wilson matrix within the overlap operator did so far not allow to simulate on realistic, four dimensional lattices, using dynamical overlap simulations, because the computational power needed to invert the overlap operator, the time consuming part of the Hybrid Monte Carlo (HMC) algorithm, is too big.

In the past, we have been developing preconditioning and relaxation techniques which reduce the time needed for the inversion of the overlap operator by over a factor of 4, bringing the simulation of dynamical overlap fermions on medium-size lattices within the range of Teraflop computers.

In this paper we apply the HMC algorithm to overlap fermions. We approximate the matrix sign function using the Zolotarev rational approximation, treating the smallest eigenvalues of the Wilson operator exactly. We then derive the fermionic force for the overlap operator, presenting a new method for the treatment of zero crossings of the eigenmodes of the Wilson kernel. Our method, for the first time, is able to preserve the advantageous scaling of the Hybrid Monte Carlo algorithm.

Finally, we test our algorithm on small lattices with up to 12^4 sites at relatively small masses.

IC/MP199/020: Nonlinear eigenvalue problems.

Organiser: Heinrich Voss (TU Hamburg–Harburg, Germany)
Co-organiser: Elias Jarlebring (TU Braunschweig, Germany)

The nonlinear eigenvalue problem $T(\lambda)x = 0$, where $T : D \to \mathbb{C}^{n\times n}$ is a family of matrices depending on a parameter $\lambda \in D \subset \mathbb{C}$, arise in a wide variety of applications; e.g., sensitivity analysis of mechanical systems or micro electromechanical systems, vibrations of damped and/or rotating structures and of fluid–solid structures, the numerical simulation of semiconductor nano-structures and stability of time-delay systems and differential–difference equations.

The eight presentations of this minisymposium reflect some of the current challenges related to nonlinear eigenvalue problems and the pseudospectra of nonlinear eigenvalue problems. Systematic new linearization approaches for quadratic, and more generally polynomial eigenvalue problems are discussed that preserve internal structures such as eigenvalue symmetries. Minmax characterizations of real eigenvalues for some classes of problems are exploited for determining some extreme eigenpairs of large and sparse symmetric eigenproblems with applications to the Schrödinger equation depending rationally on the eigenparameter and to regularized total least squares problems. Two-sided Jacobi–Davidson type methods are proposed for computing eigenpairs of strongly non-Hermitean nonlinear problems, and are analyzed taking advantage of techniques from singularity theory. Structured pseudospectra are introduced for nonlinear eigenproblems including computable formulae, and are applied to the sensitivity analysis of eigenvalues of time-delay systems. Numerical methods to compute the spectrum of time-delay systems using rational interpolation are proposed, as well as some methods using pseudospectral approximations of partial retarded functional differential equations and its applications in robust control of time-delay systems.

Staircase forms and linearization of matrix polynomials. **Volker Mehrmann** (TU Berlin, Germany) IC/MT1174/020

The classical approach for the solution of nonlinear eigenvalue problems is linearization; i.e., the transformation to a larger linear eigenvalue problem. Unfortunately the classical companion forms destroy symmetry structures, while structured linearizations only work if certain eigenvalues are excluded in the original problem. We describe a new structured staircase form under unitary/orthogonal transformations for arbitrary matrix tuples and show how this can be used to determine structured linearizations.

Hyperbolic matrix polynomials and definite pencils. **D. Mackey** (Western Michigan University, USA) IC/MT2586/020

The usual definitions of definite pencil and hyperbolic quadratic polynomial make these two classes of matrix polynomial appear to be unrelated. However, it is well known that the corresponding eigenproblems have many properties in common; indeed, among matrix polynomial eigenproblems these can be regarded as the closest analogs of the standard eigenproblem for Hermitian matrices. In this talk we generalize the usual definition of hyperbolic polynomial, and see how this generalization both simplifies and unifies the notions of hyperbolic matrix polynomial and definite pencil. This connection is further strengthened by showing that a matrix polynomial is hyperbolic in this generalized sense if and only if it can be linearized by a definite pencil of a particular type.

This is joint work with Nicholas J. Higham and Françoise Tisseur of The University of Manchester, U.K.

A primal–dual Jacobi–Davidson-like method for nonlinear eigenvalue problems based on singularity theory. **Kathrin Schreiber** (TU Berlin, Germany), Hubert Schwetlick (TU Dresden, Germany) IC/MT1888/020

We present a Jacobi–Davidson like correction formula for left and right eigenvector approximations of strongly non-Hermitian nonlinear eigenvalue problems. It exploits techniques from singularity theory for characterizing singular points of nonlinear equations. Unlike standard nonlinear Jacobi–Davidson, the correction formula does not contain derivative information and works with orthogonal projectors only. Moreover, the basic method is modified in that the new eigenvalue approximation is taken as a nonlinear Rayleigh quotient obtained as root of a certain scalar nonlinear equation the existence of which is shown.

[1] Schwetlick, H. and Schreiber, K.; A primal-dual Jacobi–Davidson-like method for nonlinear eigenvalue problems. Internal Report ZIH-IR-0613, pp.1–20, Techn. Univ. Dresden, Zentrum für Informationsdienste und Hochleistungsrechnen, 2006. Submitted to *ETNA*.

Numerical simulation of the electronic structure of quantum dots. **Heinrich Voss** (TU Hamburg–Harburg, Germany) IC/MT1065/020

In semiconductor nanostructures free carriers are confined to a small region of space by potential barriers, and if the size of this region is less than the electron wavelength, the electronic states become quantized at discrete energy levels. The ultimate limit of low dimensional structures is the quantum dot, in which the carriers are confined in all three directions, thus reducing the degrees of freedom to zero.

The governing equation characterizing the relevant energy states λ and corresponding wave functions ψ is the Schrödinger equation

$$-\nabla\cdot\left(\frac{\hbar^2}{2m(\lambda)}\nabla\psi\right)+V\psi=\lambda\psi,$$

which depends nonlinearly on the eigenparameter if we assume a non-parabolic electron effective mass m.

Taking advantage of variational properties of the eigenproblem (which are inherited by finite element discretizations) it can be solved efficiently by iterative projection methods of Arnoldi or Jacobi-Davidson type combined with safeguarded iteration.

IC/MP199/020: Nonlinear eigenvalue problems. #2

Organiser: Heinrich Voss (TU Hamburg–Harburg, Germany)

(For abstract, see session #1 above.)

Pseudo-spectra for nonlinear eigenvalue problems, with application to time-delay systems. **Wim Michiels** (Katholieke Universiteit Leuven, Belgium) IC/MT2509/020

In the first part of the presentation, various definitions for pseudospectra of a nonlinear eigenvalue problem are given, where the structure of the eigenvalue problem is exploited and, if needed, additional structure can be imposed on the matrices which occur in the definition of the eigenvalue problem. Various perturbation measures are considered and computationally tractable expressions are derived. The results are applied to classes of linear delay differential systems with uncertain coefficient matrices, whose transient behaviour and stability properties are determined by the solutions of a nonlinear eigenvalue problem. Special properties of the pseudospectra of such equations are discussed and illustrated.

In the second part of talk we address stability radii of stable linear time-delay systems, which can be defined as the size of smallest destabilizing perturbations. For time-invariant perturbations computational formulae can be directly obtained from the expressions for the pseusodpectra. Next, by taking an interconnection point of view and applying ideas from L2 gain analysis, we show how formulae for the stability radii can also be derived for the case where classes of time-varying perturbations are considered.

Examples from laser physics and structural dynamics will be used throughout the presentation, to illustrate the main ideas and results.

Rational interpolation iteration for eigenvalues of a delay-differential equation. **Elias Jarlebring** (TU Braunschweig, Germany) IC/MT1040/020

We present a new method to find the eigenvalues of a *single delay delay-differential equation*; i.e., the solutions $s\in C$ and $v\in C^n$ of the characteristic equation

$$\left(-sI+A_0+A_1e^{-\tau s}\right)v=0\,.$$

The method iteratively approximates the exponential term with a rational function, which is determined by selecting interpolation points at the eigenvalue-approximations of the previous iterate. The rational approximation of the characteristic equation is a *rational eigenvalue problem* and can be solved by known methods for such problems or be transformed to a *polynomial eigenproblem*. The convergence of the iteration is demonstrated with examples together with some conservative error-bounds. The advantages of the method are investigated by comparing it to standard methods for computing the eigenvalues of delay-differential equations.

Pseudo-spectral approximations of characteristic values of partial-retarded functional differential equations. **Dimitri Breda** (Università degli Studi di Udine, Italy), Stefano Maset (Università degli Studi di Trieste, Italy), Rossana Vermiglio (Università degli Studi di Udine, Italy) IC/MT2229/020

Partial differential equations of evolution involving time delay, also called Partial Retarded Functional Differential Equations (PRFDEs), arise in many fields: population ecology, control theory, genetic regression, climate models, structured population models.

In this talk we deal with semi-linear PRFDEs restated as abstract semi-linear RFDEs

$$\frac{du(t)}{dt} = A_T u(t) + F(u_t),\ t \geq 0,$$

where A_T is the infinitesimal generator of a strongly continuous semigroup of bounded linear operators on a complex Banach space X, $F : C \to X$ is a Lipschitz map defined on the space $C = C([-r, 0], X)$ with $r > 0$, and $u_t \in C$ is given by $u_t(\theta) = u(t + \theta)$, $\theta \in [-r, 0]$.

The stability analysis of equilibrium points plays a main role in the study of PRFDEs. It is well known that the asymptotic stability of an equilibrium point can be reduced to the asymptotic stability of the zero solution of the linear equation obtained by linearizing about the equilibrium point. The linearization of the semi-linear PRFDE about an equilibrium point yields the abstract fully-linear RFDE

$$\frac{du(t)}{dt} = A_T u(t) + L\,(u_t)\,,\ t \geq 0,$$

where $L : C \to X$ is a linear bounded operator.

Recently, several numerical approaches have been proposed to approximate the characteristic values of linear RFDEs, i.e. for X finite-dimensional and $A_T = 0$. One of these approaches consists in the discretization by a pseudospectral technique of the infinitesimal generator of the semigroup of the solution operators of the RFDE. In this talk such an approach is extended to the abstract fully-linear RFDE above.

On a quadratic eigen-problem occuring in regularized total least-squares. **Joerg Lampe** (TU Hamburg–Harburg, Germany), Heinrich Voss (TU Hamburg–Harburg, Germany) IC/MT1090/020

In a recent paper Sima, van Huffel and Golub suggested a computational approach for solving regularized total least squares problems via a sequence of quadratic eigenvalue problems. Taking advantage of a variational characterization of real eigenvalues of nonlinear eigenproblems we prove the existence of a right most eigenvalue. For large problems we improve the approach of Sima et al. considerably using thick and early updates in a Nonlinear Arnoldi method.

IC/MP76/020: Iterative solution of saddle-point systems arising in PDE-constrained optimization.

Organiser: Andy Wathen (University of Oxford, UK)
Co-organiser: Walter Zulehner (Universität Linz, Austria)

Significant improvements in computational power and the development of efficient algorithms for Partial Differential Equations (PDEs) have in the last several years enabled the solution of very large scale Optimization problems with PDE constraints; that is Optimization problems in which application of the constraints involves solving a PDE problem. Such problems give rise to sequences of very large dimensional linearized problems with the well-known saddle-point structure.

Preconditioned iterative approaches for the solution of these equations are the subject of this minisymposium.

Approximate nullspace iterations for KKT systems . **Volker Schulz** (Universität Trier, Germany) IC/MT1900/020

PDE constrained optimization problems lead naturally to Karush-Kuhn-Tucker (KKT) sytems, where the nullspace of the constraints is parameterized by the degrees of freedom for optimization. This nullspace cannot be computed exactly because this would mean the solution of many state PDEs. Therefore, classical Schur complement decomposition methods for KKT systems seem to be out of question. In this talk, novel convergence results are presented for approximate nullspace Schur complement decompositions used for the iterative solution of KKT systems. The importance of this research for practical applications is demonstrated in the field of shape optimization problems.

Multigrid solvers for very-large-scale saddle-point systems. **George Biros** (University of Pennsylvania, USA) IC/MT2796/020

In this talk we present multigrid smoothers for saddle-point Euler–Lagrange equations related to inverse problems for systems governed by parabolic PDEs. Due to the problem size of these problems, we have to devise matrix-free preconditioners. Due to the ill-conditioning, efficient multigrid solvers are required. The two key components of multigrid are the intergrid transfer operators, and the smoother. Here we restrict our attention to construction of efficient smoothers for full-space formulations of the inverse problem.

Preconditioners in optimal-control problems. **Ekkehard Sachs** (Universität Trier, Germany & Virginia Tech, USA) IC/MT3573/020

Optimal control problems with PDEs lead in discretized form to large scale optimization problems. Their numerical solution with SQP methods or interior point problems often requires the solution of saddle point problems as subproblems per iteration. The choice of appropriate preconditioners for an iterative solver is important for the efficiency of the method.

We review in particular the conjugate gradient method, which is especially suitable for optimization problems and investigate the infinite dimensional setting and its consequences for finite dimensional approximations.

A block-diagonal preconditioner for a saddle-point formulation of the Maxwell equations. **Chen Greif** (University of British Columbia, Canada) IC/MT1646/020

We discuss block preconditioning techniques for iteratively solving linear systems arising from finite element discretizations of the mixed formulation of the time-harmonic Maxwell equations. The preconditioners are motivated by spectral equivalence properties of the discrete operators, but are augmentation-free and Schur complement-free. We provide a complete spectral analysis, and show that the eigenvalues of the preconditioned matrix are strongly clustered. We show that the scalar Laplacian can be used as a weight matrix, and augmented terms can be replaced by matrices that are easier to solve for. Inexact solves based on the theory of inner/outer iterations further reduce the computational cost of the solver. An efficient implementation based on multigrid in a parallel computing environment deomonstrates the scalability of proposed approach.

IC/MP214/020: Multiscale porous media: solvers.

Organiser: Mary Wheeler (University of Texas at Austin, USA)
Co-organiser: Ivan Graham (University of Bath, UK)
Co-organiser: Robert Scheichl (University of Bath, UK)

Multiphase flow, transport, and reaction in porous media have important applications in petroleum reservoir engineering and in groundwater flow. These often involve multiphase multiphysics processes across multiple temporal and spatial scales whose discretisation leads to large highly ill-conditioned linear systems. This minisymposium showcases recent advances in solvers for these systems, with emphasis on special domain decomposition, multilevel and deflation methods. It is linked to the two other minisymposia: "Multiscale porous media: discretizations" and "Multiscale porous media: applications"

Domain decomposition methods for multiscale elliptic PDEs. **Ivan Graham** (University of Bath, UK) IC/MT1739/020

In this talk we will discuss domain decomposition preconditioning for linear systems arising from finite element approximation of symmetric elliptic problems with highly variable coefficients. The work is motivated by problems arising in the computation of flow through heterogeneous media. We will give condition number bounds which demonstrate how the subdomains and coarse space basis functions should be designed in order for the methods to be robust to both the heterogeneity of the media and the mesh parameters. In particular, we give a rigorous connection between low energy basis functions and robustness to heterogeneity. The results are illustrated by examples showing the benefits of using multiscale finite element interpolation as a coarsener.

Robust coarsening for multiscale PDEs. **Robert Scheichl** (University of Bath, UK) IC/MT1735/020

We consider two-level overlapping domain decomposition preconditioners for piecewise linear finite element approximations of elliptic PDEs with highly variable coefficients, as they arise in practice, for example, in the computation of flows in heterogeneous porous media, in both the deterministic and (Monte-Carlo simulated) stochastic cases. We propose and analyse new robust coarsening strategies for these problems, e.g. based on smoothed aggregation and multiscale finite elements, and study different ways of combining the coarse solve with the local solves (i.e. additive, multiplicative and deflation). We will use and extend a recently developed general framework for analysing the resulting preconditioners to show their robustness for a variety of model situations, but we will also focus in this talk on linear algebra and parallelisation aspects. Numerical experiments will be used to illustrate the robustness and efficiency of the proposed methods and the sharpness of our theoretical results.

This is joint work with I.G. Graham and J. Van lent (University of Bath) and E. Vainikko (University of Tartu, Estonia).

Multiscale deflation solvers for flow in porous media. **Hector Klie** (University of Texas at Austin, USA), Adolfo Rodriguez (University of Texas at Austin, USA), Mary Wheeler (University of Texas at Austin, USA) IC/MT1613/020

It is a well-known fact that the ill-conditioning of linear systems arising in porous media flow applications is mainly due to the high variability and poor correlation lengths shown by most realistic permeability/porosity field distributions. This fact has been one of the main factors limiting the applicability of standard algebraic solutions for a wide range of linear systems arising in many fluid flow simulations. This work describes a novel physics-based deflation preconditioner approach for solving porous media flow problems characterized by highly heterogeneous media. The approach relies on fast-flow block solutions after rearranging the linear system coefficients into a fast-flow and slow-flow blocks from a given physically driven threshold value. This rearranging may either follow a static inspection of the permeability field or follow flow field information obtained from a lower complexity flow model (e.g., single phase-flow or streamline simulator). Hence, the preconditioner strategy is built upon the premise that flow trends (driven by the connectivity of high permeability regions) should determine the relevance of the coefficient blocks to be included in the solution process. The resulting preconditioner may alternatively be combined with a Krylov-based or domain-based deflation preconditioning stage. This additional operation allows for the removal of the negative effect that extreme (usually small) eigenvalues may have on the convergence of the Krylov iterative method. Generally, these extreme eigenvalues are associated with unresolved error frequencies due to local permeability contrasts and small flow contributions from low-permeability regions. The proposed approach is labeled as a physics-based 2-stage, deflation preconditioner (P2SDP). Numerical experiments on different permeability distributions reveal that the P2SDP is a powerful means to solve pressure systems when compared to more conventional algebraic approaches such as ILU and block preconditioners.

Projection acceleration of Krylov solvers. **Cornelis Vuik** (TU Delft, The Netherlands) IC/MT1847/020

To predict the presence of oil and natural gas in a reservoir it is important to know the fluid pressure in the rock formations. A mathematical model for the prediction of fluid pressure is given by a time-dependent diffusion equation. Application of the finite element method leads to systems of linear equations. A complication is that the underground consists of layers with very large contrasts in permeability. This implies that the symmetric and positive definite coefficient matrix has a very large condition number. Bad convergence behavior of the ICCG method has been observed, and a classical termination criterion is not valid in this problem.

Other applications, where the coefficients have large discontinuities are electrical power networks, groundwater flow, semiconductors, and electromagnetic modeling.

In this paper it is proven that the number of small eigenvalues of the IC preconditioned matrix is equal to the number of high permeable domains, which are not connected to a Dirichlet boundary. It appears that the Deflated ICCG method annihilates the effect of these small eigenvalues. A method is given to construct the corresponding projection vectors in an efficient way. Furthermore it is proven that the span of these vectors is close to the 'small' eigenspace. A theoretical investigation and numerical experiments show that the DICCG method is not sensitive to small perturbations of the projection vectors. The efficiency of the DICCG method is illustrated by numerical experiments.

Problems with large jumps in the coefficients can also be solved with a suitable (additive) coarse grid correction. In this paper we compare deflation with the additive coarse grid correction and the balancing preconditioner.

IC/MP98/021: Algorithms for high-dimensional problems.

Organiser: Josef Dick (UNSW Asia, Singapore)
Co-organiser: Frances Kuo (University of New South Wales, Australia)

Applications often require concrete algorithms for solving high dimensional problems like numerical integration, approximation, function recovery, maximum likelihood estimation, solving integral equations, pde's, sde's and so on, to name but a few.

In this double session some of the leading researchers in the field will present their newest research concerning the analysis and/or implementation of algorithms which can be used for solving some high dimensional problems.

Sparse grids for the approximation of probability densities. **Markus Hegland** (Australian National University) IC/MT1488/021

Probability densities are widely used in statistics, machine learning and stochastic modelling. They provide a tool for exploring features like clusters and moments of populations of objects. Traditional statistical techniques include histograms, kernel density estimators and (penalised) maximum likelihood methods. They all face the classical dilemma when applied to high-dimensional data: either the complexity is exponential in the dimension as in the example of histograms or the evaluation complexity is proportional to the number of data points as in the example of kernel density estimators.

Here we will discuss inference methods for (conditional) densities using stochastic process priors and several divergences. Furthermore we will introduce new graphical models based sparse grids for density approximation.

Optimal algorithms for approximation of piecewise r-smooth functions. **Leszek Plaskota** (Uniwersytet Warszawski, Poland) IC/MT4981/021

We study optimal algorithms for approximating functions (pictures) that are piecewise r-smooth, in the worst case and asymptotic settings. Traditional (nonadaptive) methods that are optimal for globally r-smooth functions are generally useless in this case. Hence one has to switch to adaptive methods to achieve best possible convergence rate, which is n^{-r} where n is the number of function evaluations.

The obtained results are very much sensitive to the metric in which the error of approximation is measured. For instance, there are no algorithms with uniform error converging to zero for discontinuous functions. If the error is meaured in the Skorohod metric (which is roughly the uniform distance between the original and slightly perturbed pictures) then there are adaptive algorithms with error n^{-r}. Similar positive results can be obtained even in the uniform norm if the functions under consideration are globally continuous.

The optimal algorithms generally use interpolation/extrapolation methods that are based on adaptively chosen samples.

On the convergence of quasi-random sampling importance resampling. **Ronald Cools** (Katholieke Universiteit Leuven, Belgium), Bart Vandewoestyne (Katholieke Universiteit Leuven, Belgium) IC/MT943/021

In this talk, we discuss the problem of generating representative point sets from a distribution known up to a multiplicative constant. The Sampling/Importance Resampling (SIR) algorithm is known to be useful in this context. The Quasi-random Sampling Importance Resampling (QSIR) scheme, based on quasi-Monte Carlo methods, is a recent modification of the SIR algorithm and was empirically shown to have a better rate of convergence. Exploiting the theory of quasi-Monte Carlo and restricting ourselves to distributions with independent and identically distributed marginals, we construct asymptotic error bounds for the QSIR scheme.

Strong tractability of multivariate integration of arbitrary high order using polynomial lattice rules. **Friedrich Pillichshammer** (Universität Linz, Austria), Josef Dick (UNSW Asia, Singapore) IC/MT989/015

We show the existence of digitally-shifted polynomial lattice rules which achieve strong tractability results for Sobolev spaces of arbitrary high smoothness. The convergence rate is shown to be best possible up to a given degree of smoothness of the integrand.

Lower-dimensional manifold detection in high-dimensional data spaces by dimension-adaptive sparse grids. **Michael Griebel** (Universität Bonn, Germany) IC/MT1332/021

High-dimensional problems and data often live in a lower-dimensional subspace or manifold with relatively small intrinsic dimension. In such cases it is possible to break the curse of dimensionality, i.e. to circumvent the exponential dependency on the high dimension in the complexity of associated algorithms, by transferring the problem approximatively into a representation which uses the intrinsic coordinates of the lower-dimensional subspace. We then may design algorithms whose complexity only depend (exponentially) on the dimension of this subspace. Unfortunately, neither the lower-dimensional subspace/manifold nor its (non-linear) coordinate system is usually known a-priori.

We discuss how such lower-dimensional manifolds can be detected by dimension-adaptive sparse grid methods.

Randomized Smolyak algorithms based on digital sequences for multivariate integration. **Gunther Leobacher** (Universität Linz, Austria), Friedrich Pillichshammer (Universität Linz, Austria), Josef Dick (UNSW Asia, Singapore) IC/MT1157/021

In this paper we consider Smolyak algorithms for high dimensional numerical integration. The quadrature rules are equal weight quadrature rules based on digital $(t, \alpha, \beta, \sigma, d)$-sequences. As those sequences can be randomized we obtain a randomized Smolyak algorithm. We consider the worst-case error in certain Sobolev spaces and show that our quadrature rules achieve the optimal rate of convergence. This result holds for the randomized as well as for the deterministic algorithm. We also show that the randomized algorithm is unbiased and that the integration error can be approximated as well.

Quasi-Monte-Carlo for Markov chain Monte-Carlo. **Art Owen** (Stanford University, USA) IC/MT970/021

There has been considerable progress recently in developing improvements to Monte Carlo methods. Quasi-Monte Carlo (QMC) methods improve MC accuracy by using a more balanced sampling. Markov chain Monte Carlo (MCMC) widens the applicability of MC to problems where we cannot sample IID from the desired distribution. The published intersection between these two methods is conspicuously small.

To use QMC points in the MCMC context, one seeks to achieve equidistribution in $[0,1]^\infty$. We show that some but not all QMC points give rise to consistent estimates in Metropolis-Hastings algorithms, including the Gibbs sampler. The suitable points are completely uniformly distributed (CUD). In some numerical examples, variance reduction factors seen range from just over 2 to just over 240. The Gibbs sampler seems to be well suited to QMC inputs.

This is joint work with Seth Tribble.

Finite-order lattice rules can be dangerous. **Ian Sloan** (University of New South Wales, Australia) IC/MT949/021

Lattice rules constructed by the component-by-component algorithm are known to provide an effective approximation scheme for many high-dimensional problems formulated as integrals over the d-dimensional unit cube. In this talk it is demonstrated that the use of so-called finite-order weights can be dangerous for applications. The danger lies in the fact that a lattice rule constructed with say order-2 weights can have very bad 3-dimensional projections. As a result, if the integrand cannot be expressed exactly as the sum of functions of two variables at a time then there is no guarantee of convergence as the number of integration points approaches ∞.

IC/MP330/021: Approximate algebraic methods for computer-aided geometric design.

Organiser: Tor Dokken (SINTEF, Norway)

Although the origin of algebraic geometry was to solve geometric problems of daily life, current research is addressing problems described in homogeneous coordinates and complex spaces. The introduction of computers more than five decades ago triggered research in Computer Aided Geometric Design (CAGD). This research has always been focused on what is feasible to compute on available commodity computers. The continuous increase in computational performance has also triggered demands for better quality and higher accuracy in Computer Aided Design systems, especially with respect to surface intersection algorithms.

To try to satisfy these demands researchers in classical Algebraic Geometry and researches in CAGD have in recent years joined forces to address challenges related to geometry representation and interrogation in producing industries. The EU IST-2001-35512 project *Intersection algorithms for geometry based IT-applications using approximate algebraic methods* addressed the problems of problematic intersections in CAD-systems. The focus was surface self-intersections and situations where surfaces are near parallel in intervals along the intersection curves. The project addressed the challenges from the viewpoint of exact computations, semi-numeric computations and a numeric recursive subdivision approach. After the project end the project partners have continued their research. The mini-symposium will focus on experiences of such a focused research project and results from and after the project. It will address:

- approximate implicitization, how to approximate parametric surfaces by real algebraic surfaces;
- exact, numeric and recursive intersection algorithms;
- resolving topological questions in practice about real curves and surfaces;
- use of multi-core CPUs and programmable graphics cards for improving quality and performance of intersection algorithms.

The use of approximate implicitization in recursive surface-intersection algorithm. **Tor Dokken** (SINTEF, Norway) IC/MT1331/021

Most published work on NURBS surface intersection address *transversal intersections*, situations where the surface normals of the surfaces interesected are well separated along all intersection curves. NURBS - NonUniform Rational B-splines is the standard representation for parametric surfaces in CAD. For transversal intersections the divide and conquer strategy of recursive subdivision, Sinha's theorem and the convex hull property of NURBS surfaces efficiently identify all intersection branches. However, in *singular or near singular intersections*, situations where the surfaces are parallel or near parallel in an intersection region, along an intersection curve or in an intersection point, even deep levels of subdivision will frequently not sort out the intersection topology.

The talk will focus on two novel approaches to address this situation:

- Use of *approximate implicitization* for separation of near parallel curves or surfaces, and for detecting a monotone relation between two curves or two surfaces. Approximate implicitization denotes methods that within a region of interest approximate a parametric curve or surface with respectively an real algebraic curve or surface of lower degree than the exact algebraic representation.
- Use of parallel processing on multi-core CPUs or programmable graphic cards (GPUs) to establish when the intersection is transversal, and when the intersection is singular or near singular. Many standard GPUs have currently one to two orders of magnitude higher computational performance than a single-core CPU. Such performance can be used for simplistic subdivision of surfaces to detect intersections that are clearly transversal and identify intersections that possibly are singular or near singular.

Gauss–Newton-type techniques for l^p approximation. **Martin Aigner** (Universität Linz, Austria), Bert Juttler (Universität Linz, Austria) IC/MT1846/021

We consider the problem of fitting a parametric or implicitly defined curve or surface to given scattered data. In order to minimize the influence of noise and of outliers, it is desirable to consider the l^p norm of the error vector for small values of p (p≥1). On the other hand, in order to minimize the maximum error, it is useful to consider l^p norms for large values of p. In this talk we derive Gauss-Newton-type techniques for minimizing these l^p norms and analyze their relation to the method of iteratively reweighted least-squares fitting.

Mixing symbolic and numerical approaches for the surface-to-surface intersection problem. **Mario Fioravanti** (Universidad de Cantabria, Spain), Laureano Gonzalez-Vega (Universidad de Cantabria, Spain) IC/MT2019/021

The Surface-to-Surface Intersection Problem is one of the most critical tasks in Computer Aided Geometric Design. In this talk it will be shown how the efficiency of current methodologies dealing with this problem can be improved by combining an algebraic/symbolic framework with efficient and robust numerical techniques.

The algebraic/symbolic framework will be used to translate the computation of resultants, subresultants, discriminants, etc. (needed when approaching this problem symbolically) to one or several generalized eigenvalue problems and SVD computations. The framework requires only the values of the involved polynomial at some set of points (i.e. the monomial description of them may not be available). This framework will guide the numerical solving of the above mentioned problems providing thus a certificate of the topological correctness of the output.

As particular cases, the following problems will be also shown to be solved by using this approach:

- Computing the topology of $f(x,y)=0$.
- Computing the topology of the offset of $f(x,y)=0$ to distance d.
- Computing the intersection points between the offsets of planar parametric curves.

Symbolic–numeric methods for semi-algebraic shapes. **Bernard Mourrain** (INRIA Rocquencourt, France) IC/MT2104/021

We are interested by shapes represented by semi-algebraic models, such as parameterized curves and surfaces which are the basis of classical geometric modeler, but also by implicit representations, which allows compact and powerful representations of geometric objects. Performing geometric operations on these models require on one hand topological computation and on the other hand numerical approximation. In particular, it leads to the manipulation of roots of polynomial equations. We are going to detail methods which exploit a duality between exact implicit and approximate computation in these problems and show how to combine for analysing singularities of such objects or computing their topology, (self)-intersection curves. We will illustrate it by some experiments with the library SYNAPS, integrated in the modeler AXEL.

IC/MP1067/021: Sparse grids for high-dimensional approximation.

Organiser: Michael Griebel (Universität Bonn, Germany)
Co-organiser: Markus Hegland (Australian National University)
Co-organiser: Christoph Schwab (ETH Zürich, Switzerland)

Sparse grids are a special discretization technique for the approximation of high-dimensional functions. Based on a sparse tensor product construction they employ only $O(N(\log N)^{d-1})$ grid points, where N denotes the number of points in one dimension and d the number of dimensions. The achieved accuracy is nearly the same as the one obtained on conventional uniform grids provided that the smoothness assumption of bounded mixed derivatives is fulfilled. Thus sparse grids allow to cope with the curse of dimensionality of grid based approaches to a certain extent. The minisymposium will present an overview of the approach with an emphasis on recent developments in the theory of the sparse grid combination technique and on applications of sparse grids for the solution of high-dimensional partial differential equations and in machine learning.

Deterministic simulation for asset–liability management in life insurance. **Markus Holtz** (Universität Bonn, Germany) IC/MT3824/021

New regulations and a stronger competition have increased the importance of stochastic asset-liability-management models for insurance companies in recent years. In this talk, we propose deterministic integration schemes for the simulation of such models, such as quasi-Monte Carlo and sparse grid methods. Numerical examples demonstrate that these deterministic methods outperform Monte Carlo simulation even for long time horizons. The success of the deterministic integration schemes can be explained using the concept of the effective dimension and the concentration of measure phenomenon. Further efficiency improvements are achieved by dimension-adaptive sparse grid algorithms as we finally demonstrate by numerical examples.

Sparse finite elements for radiative transfer. **Gisela Widmer** (ETH Zürich, Switzerland), Ralf Hiptmair (ETH Zürich, Switzerland), Christoph Schwab (ETH Zürich, Switzerland) IC/MT3879/021

The linear radiative transfer equation, a partial differential equation for the intensity $u(\mathbf{x},\mathbf{s})$, with independent variables $\mathbf{x}\in D\subset\mathbb{R}^n$, $n=2,3$ and ß $\in S^2:=\{\mathbf{y}\in\mathbb{R}^3:|\mathbf{y}|=1\}$, is considered in the $n+2$-dimensional tensor product domain $D\times S^2$.

We propose and analyse an adaptive multilevel Galerkin FEM for the efficient numerical solution of the radiative transfer equation. Our method is based on: a) a stabilized variational formulation, and on b) so-called sparse tensor products of two hierarchic families of Finite Element spaces in $H^1(D)$ and in $L^2(S^2)$, respectively.

Specifically, we use wavelet decompositions of Finite Element spaces of continuous, piecewise linear functions on simplicial triangulations of the physical domain D and of discontinuous, piecewise constants on S^2.

We describe the details of the sparse tensor product spaces with adaptive, anisotropic mesh refinements in $D\times S^2$. A convergence analysis under strong regularity assumptions on the solution shows that the method converges with essentially optimal asymptotic rates while its complexity grows essentially only as that for a linear transport problem in $\mathbb{R}^n$. Numerical experiments for $n=2$ agree with the convergence and complexity analysis of the method and show its performance to be superior to the discrete ordinate method.

Sparse finite element approximation of high-dimensional transport-dominated diffusion problems. **Endre Süli** (University of Oxford, UK), Christoph Schwab (ETH Zürich, Switzerland), Radu-Alexandru Todor (ETH Zürich, Switzerland) IC/MT4954/021

Partial differential equations with nonnegative characteristic form arise in numerous mathematical models in science. In problems of this kind, the exponential growth of computational complexity as a function of the dimension d of the problem domain, the so-called "curse of dimension", is exacerbated by the fact that the problem may be transport-dominated.

We develop the numerical analysis of stabilized sparse tensor product finite element methods for such high-dimensional, non-self-adjoint and possibly degenerate second-order partial differential equations, using piecewise polynomials of degree $p\geq 1$. Our convergence analysis is based on new high-dimensional approximation results in sparse tensor-product spaces. By tracking the dependence of the various constants on the dimension d and the polynomial degree p, we show in the case of elliptic transport-dominated diffusion problems that for $p\geq 1$ the error-constant exhibits exponential decay

as $d \to \infty$. In the general case when the characteristic form of the partial differential equation is non-negative, under a mild condition relating p to d, the error constant is shown to grow no faster than $\mathcal{O}(d^2)$. In any case, the sparse stabilized finite element method exhibits an optimal rate of convergence with respect to the mesh size h_L, up to a factor that is polylogarithmic in h_L.

The talk is based on a recent paper available from: http://web.comlab.ox.ac.uk/oucl/publications/natr/NA-07-04.html.

Probability-density estimation using sparse grids. **Stephen Roberts** (Australian National University) IC/MT2830/021

In this talk we will discuss the use of sparse grid spaces for the estimation of high dimensional probability density functions. We will consider histosplines, L^2 projections and simple direct estimates via the cumulative distribution function. We investigate the convergence properties of these methods and show, for instance, that for a smooth enough underlying probability density function, the approximation error is $\log(N)^{d-1}N^{-2}$, where N is the dimension of the underlying sparse grid approximating space. The use of classical sparse grids allows us to practically deal with data sets with up to 15 dimensions. The methods are demonstrated on a 10 dimensional data collection containing information on vegetation cover and various geographical features.

IC/MP1067/021: Sparse grids for high-dimensional approximation. #2

Organiser: Michael Griebel (Universität Bonn, Germany)

Co-organiser: Christoph Schwab (ETH Zürich, Switzerland)

(For abstract, see session #1 above.)

Stochastic Galerkin method with sparse polynomial-chaos expansion. **Marcel Bieri** (ETH Zürich, Switzerland), Christoph Schwab (ETH Zürich, Switzerland) IC/MT1304/021

We consider a deterministic finite element (FE) solution algorithm for solving stochastic elliptic boudary value problems of the form

$$\begin{cases} -\mathrm{div}(a(x,\omega)\nabla u(x,\omega)) = f(x) & \text{in } D,\ u(x,\omega)|_{x\in\partial D} = 0, \quad P\text{-a.e. } \omega\in\Omega. \end{cases}$$

A separation of deterministic and stochastic variables is achieved via a Karhunen-Loève expansion, which leads to a high-dimensional but now purely deterministic problem. To overcome this high complexity we propose a sparse polynomial chaos expansion (SPC) to handle the stochastic parameters whereas for the spatial part a generic FE-solver can be used. Mathematical as well as numerical results will be presented to show convergence rates of the proposed algorithm.

An optimised sparse grid combination technique for eigenvalue problems. **Jochen Garcke** (TU Berlin, Germany) IC/MT1893/021

Recently an optimised combination technique for regression applications in machine learning was introduced. The original combination technique employs solutions on a certain sequence of (small) grids, a sparse grid solution is then obtained by addition of these partial solutions with combination coefficients which depend on the involved grids. For regression this approach shows instabilities in certain situations and is not guaranteed to converge with higher discretisation levels. In the case of the optimised combination technique the coefficients also depend on the function to be representend, a nonlinear approach, with this approach these instabilities disappear. In this talk I will show how to transfer the idea of an optimised sparse grid combination technique to eigenvalue problems. Besides the potential for improved accuracies the optimised combination coefficients also simplify the normalisation of the partial eigenfunctions. This arises since only the eigenspace is clearly defined, i.e. the partial eigenfunction have to be normalised to able to be combined in a suitable way, the optimised combination coefficients automatically take care of this issue. Numerical results for the Schrödinger equation in the case of hydrogen (in 3 space dimensions) and helium (in 6 space dimensions) are shown.

An efficient sparse-grid method for the high-dimensional Fokker–Planck equation. **Christian Feuers** (Universität Bonn, Germany) IC/MT2731/021

Numerical methods to solve the high-dimensional Fokker–Planck-equation are limited by the so called *curse of dimension'*, which restricts applications to three, maybe four space dimensions. We propose a sparse grid method for higher dimensions in order to benefit from the reduced grid complexity $O(N\log^{d-1}N)$ instead of $O(N^d)$ for classical methods. We employ timestepping schemes with variable step-size control in time and a sparse grid galerkin method in space for each time step. New matrix–vector-product algorithms for the semi-orthogonal prewavelet basis reduce the typically required 2^d grid traversals to just a constant number. We present efficient hash-based storage techniques which allow to solve the linear systems without influence of the dimension to storage requirements. While the number of iterations is known to be independend of the mesh width, its dependence on the problem dimension is discussed based on numerical experiments. The accuracy of the method is analysed by means of higher dimensional model problems. Finally, we apply the method to stochastic models in finance and present numerical results.

The combination technique and some generalisations. **Markus Hegland** (Australian National University), Jochen Garcke (TU Berlin, Germany) IC/MT4955/021

Sparse grids often effectively address the curse of dimensionality. When solving the equations for sparse grid approximations, however, one has to solve linear systems of equations which lack the typical banded or block structure which reflects the symmetry of regular grids. It has been found in the past that simple combinations of solutions on regular subgrids of a sparse grid frequently provide a good approximations to sparse grid solutions. These combinations are exact for interpolation problems, have been shown to lead to an extrapolation technique for the Poisson problem but they can also fail spectacularly, especially when applied in high-dimensional situations for adaptive sparse grids.

In the talk I will discuss an analysis of the combination technique using a projection framework and the C/S decomposition. This analysis provides connections between geometric properties and the errors of the combination technique. It will be seen how the combination technique can be improved, and we will in particular discuss the Opticom technique which uses optimal combination coefficients which are adapted to the problem and data.

This is joint work with Jochen Garcke and Vivien Challis.

IC/MP137/022: Multivariate numerical integration.

Organiser: Ronald Cools (Katholieke Universiteit Leuven, Belgium)

Integrals appear in many mathematical models and can seldom be calculated analytically. The numerical approximation of integrals is therefore one of the corner stones of numerical analysis. As computers become more powerful every day, researchers start thinking about problems nobody dreamed about some years ago, resulting in e.g. integrals with hundreds of variables.

In this minisymposium we will focus on recent developments in this area, ranging from new approaches for the construction of basic integration rules (cubature formulas) to techniques that are tailored to the application.

A cardinal function algorithm for computing cubature points. **Mark Taylor** (Sandia National Laboratories, USA) IC/MT1766/022

An effective method for constructing quadrature and cubature formulas is to numerically solve a nonlinear set of equations for the quadrature points and their associated weights. Newton's method is often used, combined with symmetry conditions to reduce the number of equations and unknowns. Here we present two improvements to this approach: We write the equations using a cardinal function basis which allows us to treat the quadrature weights as dependent variables and remove them, as well as an equivalent number of equations, from the numerical optimization procedure. Then, in the triangle, we construct initial conditions for Newton's method which approximate the pluri-potential theory extremal measure. We give results for the triangle, where for all degree $d \leq 25$, we find quadrature formulas which have positive weights and contain no points outside the triangle. Seven of these quadrature formulas improve on previously known results.

We also use this algorithm to construct cubature formulas specialized for a high-order mass-lumped finite element method (Cohen, Joly and Tordjman, 1995) This method requires cubature formulas with strength $2d$ to have $3d$ points along the boundary. Such formulas have previously been computed up to $d = 5$ (Mulder, 2000) and we extend these results to $d = 6, 7$.

elrint3d: an automatic 3D cubature routine. **Ian Robinson** (La Trobe University, Australia) IC/MT1631/022

We describe an automatic algorithm for three-dimensional cubature over quite general regions that is non-adaptive and based on an embedded lattice augmentation sequence. The algorithm is shown to be extremely efficient and effective for a wide range of functions, including smooth functions and functions with singularities at a vertex or along a boundary of the integration region.

Adaptive quasi-Monte Carlo methods for fast evaluation of contingent claims. **Ben Waterhouse** (University of New South Wales, Australia) IC/MT1489/022

The area of numerical integration is of great interest to practitioners of mathematical finance. Many integration problems encountered in mathematical finance involve integrands which are constant for large regions of the domain. This is common for derivatives which are *rare*, such as an out-of-the-money call option with a high strike price, or a digital option which is constant almost everywhere. MC and QMC methods are blind to the pay-off function and will sample throughout the domain. We would like to create methods which sample adaptively and which seek out the *interesting* regions of most variation first.

For the MC approach there are methods such as stratified sampling which will find the regions which are most important. These approaches often become much less attractive as the *curse of dimensionality* sets in.

For QMC methods, comparatively little has been done in the area of adaptive sampling. The work of Dahl proposed an adaptive algorithm for evaluation of contingent claims however it did not outperform traditional QMC methods for problems of moderate dimension. The work of Schuerer applied the ideas of the MISER and VEGAS algorithms for MC points to the QMC points. The results in this paper showed that the adaptive algorithm was beneficial for problems with dimension up to 5.

In this talk, we propose a similar algorithm which exploits the observation that many high-dimensional integrands can be written as integrands with low effective dimension. This means that we need not adaptively sample over all dimensions, but rather only those few which are of most importance. We see that by exploiting the net properties of Sobol' points and other (t, m, s)-nets, we may achieve improvements in convergence of an order of magnitude or more over traditional QMC methods. Moreover, it can be used for problems with a nominal dimension in the hundreds or higher.

Computation of Feynman loop integrals. **Elise de Doncker** (Western Michigan University, USA) IC/MT3594/022

We include a survey of the authors' and related work on multivariate integration and extrapolation techniques for the computation of Feynman loop integrals. Loop integrals are required for perturbation calculations in high energy physics, as they contribute corrections to the scattering amplitude and the cross section for the collision of elementary particles.

The term "loop" refers to the occurrence of one or multiple loops in the corresponding Feynman diagrams. In earlier work we studied the application of extrapolation based techniques to the computation of one-loop three-point (vertex) and four-point (box) diagrams, and two-loop planar (ladder) vertex diagrams. We will furthermore present more recent results for two-loop non-planar (crossed) vertex diagrams.

The integrals are particularly difficult as the integrand generally exhibits a singularity within the integration domain. The integral approximation is obtained in the limit as the value of a parameter, epsilon, in the integrand tends to zero. This involves the numerical evaluation of a sequence of integrals for decreasing epsilon, and a procedure for convergence acceleration.

We use "iterated" integration to calculate the multivariate integrals. Various one- and multi-dimensional integration methods can be combined and used in different sets of coordinate directions. We found that standard multi-dimensional integration techniques do not deliver the required results for this application. The combined integration and extrapolation methods aim for an automatic calculation, where little or no analytic manipulation is required before the numeric approximation.

This work is performed in cooperation with: Y. Shimizu (Grad. Univ. for Advanced Studies, Hayama, Japan); J. Fujimoto, T. Ishikawa and F. Yuasa (High Energy Accelerator Research Organization, Tsukuba, Japan); N. Hamaguchi (Hitachi, Ltd., Software Division, Totsuka-ku, Yokohama, Japan).

IC/MP96/022: Modern constructions of low-discrepancy sequences.

Organiser: Friedrich Pillichshammer (Universität Linz, Austria)
Co-organiser: Peter Kritzer (Universität Salzburg, Austria)

In many applications, notably quasi-Monte Carlo integration, point sets in the high dimensional unit cube with excellent distribution properties are required. A common measure for the quality of the distribution of a point set is the so-called discrepancy. Informally one will call a point set a low discrepancy point set if its discrepancy is of order $O((\log N)^s/N)$, where N is the cardinality of the point set and s is the dimension.This two-session minisymposium considers the construction and analysis of low discrepancy sequences, such as digital nets, lattice point sets and others. Furthermore, different measures of the quality of distribution of low discrepancy point sets are analyzed.

This minisymposium is closely related to the minisymposia "Algorithms for high dimensional problems" and "Complexity of high dimensional problems".

On the L_2-discrepancy of van der Corput sequences. **Henri Faure** (Université de la Méditerrannée Aix-Marseille II, France) IC/MT1013/0

Van der Corput sequences in arbitrary bases are the prototype for the construction of low discrepancy sequences widely used in numerical integration and quasi-Monte Carlo methods. Many people in the last few years have paid great attention to the behaviour of different generalizations of van der Corput sequences, especially in base two. In this communication, we will present a survey of the previous results concerning the L_2-discrepancy and then, we will introduce a method which allows to recover some results in base two and to generalize them to other bases. Hopefully, the method should also provide the answer to a recent conjecture on the L_2-discrepancy of shifted van der Corput sequences in base two (Kritzer-Pillichshammer, 2005).

Construction of digital nets based on propagation rules for OOAs. **Rudolf Schürer** (Universität Salzburg, Austria) IC/MT1195/0

(t,m,s)-*nets* are a powerful tool for the generation of low-discrepancy point sets. Based on the digit expansion of the points of a net an equivalent combinatorial object can be obtained, namely a certain subclass of an *ordered orthogonal array* (*OOA*).

Many constructions and propagation rules for nets can alternatively be formulated in the language of OOAs. In this setting it becomes apparent that these methods match well-known constructions for *orthogonal arrays* (*OAs*), which are the special case of OOAs with depth $T = 1$, whereas nets correspond to the case with depth T equal to the strength k of the OOA.

Most previous work focuses either on nets, OAs, or on obtaining a net directly from an OA. We discuss new constructions of nets that are based on OOAs with a depth strictly between 1 and k. Using a combination of such methods we obtain new nets with parameters superior to earlier results.

On linear-programming bounds for nets. **Horst Trinker** (Universität Salzburg, Austria), Wolfgang Schmid (Universität Salzburg, Austria) IC/MT1556/0

It is well known that there are close connections between low-discrepancy point sets and sequences at the one side and certain combinatorial and algebraic structures at the other side. E.g., Niederreiter (1992) showed the equivalence between $(t,t+2,s)$-nets and orthogonal arrays (OAs) of strength 2. Some years later this was generalized and made precise in the work of Lawrence, Mullen, and Schmid by introducing ordered orthogonal arrays (OOAs). This large class of combinatorial structures yields both new constructions and bounds for the existence of nets and sequences.

As in the case of linear codes and OAs, the linear programming (LP) bound is a very strong bound for OOAs and consequently for nets and sequences. The LP bound for OOAs was first derived by Martin and Stinson (1999).

Calculating LP bounds on OAs and OOAs in exact arithmetic is very time-consuming. We have studied different approaches for reducing the computing time and will give a survey of our results.

For OAs in basis $q = 2$ Bierbrauer et al. (1999) have shown that the dual Plotkin bound is optimal in certain parameter ranges, i.e. the LP bound equals the dual Plotkin bound for these parameters. We will extend this result for $q \geq 3$ by giving a sufficient condition for the optimality of the dual Plotkin bound.

Numerical investigations of hyperplane nets. **Gottlieb Piršić** (RICAM Linz, Austria) IC/MT1419/0

Cyclic nets and hyperplane nets are a recently defined class of digital nets, introduced by Niederreiter and further investigated by Dick, Pillichshammer and Pirsic.

Their definition has some relations to coding theory and is conceptionally quite simple. Nevertheless, indicated by some theoretical results, they seem to range through a fairly large subspace of all posssible digital nets.

In the talk some numerical investigations will be presented that shall aim at supporting this feeling. In particular, hyperplane nets constructed by the component-by-component method shall be considered, investigating the relations between the chosen weight structure and the t-parameter.

A new quadrature using integration lattices. **Rong-Xian Yue** (Shanghai Normal University, PR China) IC/MT1509/0

In this paper we propose a new quadrature rule via approximating Fourier coefficients of variable transformed integrand with multidimensional integration lattice. The error analysis is derived for the proposed rule. A comparison is done between the new rule and the periodizing transformation methods. It is shown that the new rule improves the periodizing transformation methods.

This is a join work with Professor Fred J. Hickernell and Xiaoyan Zeng (Department of Applied Mathematics, Illinois Institute of Technology, Chicago, USA).

On component-by-component constructions. **Dirk Nuyens** (Katholieke Universiteit Leuven, Belgium), Ronald Cools (Katholieke Universiteit Leuven, Belgium) IC/MT1738/0

Since the initial work by Sloan and his collaborators on the component-by-component construction of good lattice rules, a lot of variations on this theme have been published. These include various function spaces, prime and composite number of points, intermediate-rank rules, polynomial lattice rules and extensible rules. In this talk we look at all these different constructions and how they connect to the fast component-by-component construction variant.

Construction of low-discrepancy point sets of small size. **Michael Gnewuch** (Universität Kiel, Germany) IC/MT1598/0

The worst-case error of high-dimensional numerical integration of certain function classes is intimately related to the star-discrepancy via inequalities of Koksma-Hlawka type. The essence here is that sample points with small discrepancy lead to small integration errors.

There are many constructions of n-point sets in the d-dimensional unit cube $[0,1]^d$ known whose star discrepancy is bounded from above by $O(n^{-1}\ln(n)^{d-1})$. This upper bound is believed to be asymptotically optimal. However, it is only helpful for n exponentially large in d, since $n \mapsto n^{-1}\ln(n)^{d-1}$ is an increasing function for $n \le e^{d-1}$. Additionally, for many constructions the implicit constants in the O-notation depend critically on d.

In high-dimensional numerical integration one cannot afford to use a number of sample points exponentially in d. Furthermore, large constants are undesired. Therefore it is of interest to find useful upper bounds for the smallest possible star- discrepancy of moderate sample sizes, and to construct small samples satisfying these bounds. Heinrich, Novak, Wasilkowski and Woźniakowski (2001) proved the bounds

$$d_\infty^*(n,d) \le Cd^{1/2}n^{-1/2} \quad \text{and} \quad n_\infty^*(\varepsilon,d) \le C^2 d\varepsilon^{-2},$$

where $d_\infty^*(n,d)$ is the smallest possible star-discrepancy achieved by n points and $n_\infty^*(\varepsilon,d)$ is the cardinality of the smallest sample guaranteeing a star-discrepancy less or equal to ε. In the second bound the dependence on d is optimal. A drawback here is that so far no reasonable estimate for the universal constant C has been published. Furthermore, the proof of the bounds is probabilistic and not constructive. In the same paper the authors used a probabilistic argument based on Hoeffding's inequality that leads to asymptotically slightly weaker bounds with explicit small constants. By using reasonably good δ-covers these estimates have been improved by Doerr, Gnewuch and Srivastav (2005) to

$$d_\infty^*(n,d) \le kd^{1/2}n^{-1/2}\ln(n)^{1/2} \quad \text{and} \quad n_\infty^*(\varepsilon,d) \le k^2 d\varepsilon^{-2}\ln(\varepsilon^{-1}),$$

with a small konstant k (essentially we have $k=\sqrt{2}$). The probabilistic approach here has the advantage that it can be derandomized to construct small samples satisfying these bounds. This has been done by Doerr, Gnewuch and Srivastav (2005). The algorithm given there is essentially a point-by-point construction using the method of conditional probabilities and pessimistic estimators.

Our new approach is based on special δ-covers and on recent results on generating randomized roundings with cardinality constraints by Doerr (2006). Compared with the algorithm from Doerr et al. the new algorithm is easier to implement and has a reasonably better running time.

This is joint work with Benjamin Doerr.

Koksma–Hlawka-type inequalities of fractional order. **Josef Dick** (UNSW Asia, Singapore) IC/MT2061/0

The Koksma-Hlawka inequality states that the error of numerical integration by a quasi-Monte Carlo rule is bounded above by the variation of the function times the star-discrepancy. Here we relax the smoothness assumptions required in the Koksma-Hlawka inequality. We introduce Banach spaces of functions whose fractional derivative of order $\alpha > 0$ is in L_p. We show that if α is an integer and $p = 2$ then one obtains the usual Sobolev space. Using these fractional Banach spaces we generalize the Koksma-Hlawka inequality to functions whose partial fractional derivatives are in L_p.

IC/MP242/023: Robust integral equation methods for high-frequency problems.

Organiser: Ivan Graham (University of Bath, UK)
Co-organiser: Stephen Langdon (University of Reading, UK)

In this minisymposum we showcase recent advances in the design, analysis and implementation of frequency-robust integral equation methods for acoustic and electromagnetic wave scattering problems. Traditional methods for these problems, based on (piecewise) polynomial approximations, suffer from lack of robustness, i.e. the number of degrees of freedom typically has to increase proportional to the frequency. Better methods, which in some sense take account of the asymptotic behaviour of the solution at high frequency, have been proposed and resulting challenges (arising both in the analysis of these new methods and in their extension to practical geometries) will be the subject of this minisymposium.

High-frequency scattering by curvilinear polygons. **Stephen Langdon** (University of Reading, UK), Mosiamisi Mokgolele (University of Reading, UK), Simon Chandler-Wilde (University of Reading, UK) IC/MT1767/023

For problems of acoustic scattering by sound soft convex polygons, it has recently been demonstrated by Chandler-Wilde and Langdon that by including plane wave basis functions supported on a graded mesh in the approximation space, with smaller elements closer to the corners of the polygon, convergence rates that depend only logarithmically on the frequency of the incident wave can be achieved. In this talk, we investigate the extension of these ideas to problems of scattering by curvilinear polygons.

An hp-BEM for high-frequency scattering by convex polygons. **Markus Melenk** (TU Wien, Austria), Stephen Langdon (University of Reading, UK) IC/MT1752/023

Time harmonic accoustic scattering by a convex polygon is considered. S. Chandler-Wilde and S. Langdon have recently proposed an integral equation based method for the high frequency scattering problem. Using a detailed regularity analysis of the solution, they were able to design an h-version trial space that has approximation properties that depend only logarithmically on the wave number. The key features are a) the ability to identify the leading order (in the wave number) behavior of the solution and b) a precise characterization of the solution behavior near the vertices of the polygon. Since the approximation order is fixed, the achievable convergence rate is algebraic. In this talk, we extend their work to the hp-version of the BEM. It is shown that the solution can be approximated at an exponential rate from the trial space; the problem size required to achieve a given accuracy grows only logarithmically with the wave number. In this talk, we also address the question of how to set up the stiffness matrix with work independent of the wave number.

Bounds on oscillatory integral operators from high frequency. **Marko Lindner** (University of Reading, UK), Stephen Langdon (University of Reading, UK) IC/MT1753/023

The development of efficient numerical methods for the solution of high frequency scattering problems is an area that has received an enormous amount of recent interest. Some new integral equation methods (e.g. the methods proposed by Bruno, Geuzaine, Monro, Reitich 2004; Dominguez, Graham, Smyshlyaew 2006; Chandler-Wilde, Langdon 2006) have led to a dramatic reduction in the number of degrees of freedom per wavelength required to achieve an accurate solution, compared with more standard schemes. However, one theoretical question that remains to be answered for many of these schemes is the question of how the integral operators (both continuous and discrete) behave as the wavenumber tends to infinity. Numerical results appear to indicate that in many cases the dependence of the operator norms on the wavenumber may not be too severe. In this talk we discuss the derivation of some bounds on the norms of highly oscillatory integral operators arising from scattering problems, and we place these results in the context of stability and convergence estimates for approximation methods.

High-order boundary integral methods for Maxwell's equations using microlocal discretization and fast multipole methods. **Eric Darrigrand** (Université de Rennes I, France), Ludovic Gatard (Université de Bordeaux, France), Katherine Mer-Nkonga (Commissariat à l'Energie atomique, France) IC/MT1571/023

This paper deals with an efficient method used to solve the integral equations of B. Després regarding the time-harmonic Maxwell's equations in unbounded exterior domain for high frequencies. Our work consists in improvements of the coupling of the Microlocal Discretization (MD) and the Fast Multipole Method (FMM) using a high-order finite-elements approximation and filtering the transfer functions of the FMM which involves privileged directions in that application. The integral formulation of B. Després offers the advantage of a linear system which is well conditioned, hermitian and positive definite. This enables us to use methods based on the conjugate gradient. The Microlocal Discretization introduced by T. Abboud, J.-C. Nédélec and B. Zhou consists in an approximation of the phase of the unknown such that the new unknown is strongly less oscillating. Such a consideration leads to a discretization with a coarser mesh for the interpolation of the unknown. However, the calculation involved in the resolution of the system still requires a fine approximation of the geometry. A first work consisted in considering a double mesh: the unknown was defined on a coarse mesh and the approximation of the geometry on a fine mesh, both of them made of plane triangles. The matrix of reduced size was evaluated using a multilevel FMM (MLFMM). Though the first numerical results were very encouraging, they were not accurate enough for some applications. One could expect such observation because of the error estimates investigated by T. Abboud et al. A use of high-order finite elements which required an adaptation of the MLFMM, overcame that lack of accuracy. Moreover, a filter of the transfer functions of the MLFMM reduced the cost of the most expensive step of the MLFMM. After a thorough study of the complexity, we optimized those improvements of the coupling MD and MLFMM to obtain an accurate method of calculation of the matrix with a quasi-linear complexity.

Robust boundary-integral methods for high-frequency acoustic scattering. **Ivan Graham** (University of Bath, UK) IC/MT2377/023

In this talk we discuss the numerical solution of the problem of acoustic plane wave scattering by a 2D convex smooth sound-soft object using hybrid numerical-asymptotic methods. In recent joint work with Victor Dominguez and Valery Smyshlyaev we developed Galerkin methods with oscillatory basis functions for this problem and proved that the resulting discretisations are essentially uniformly accurate independently of the wave number. A key component of the analysis is a proper description of the asymptiotic behaviour of the solution in a format suitable for numerical analysis. This requires some further development of the classical asymptotics results for this problem. In this talk we describe the required asymptotics results and how they feed in to the design of robust numerical methods. The talk of Victor Dominguez in this minisymposium will give more deatils of the robust numerical method, its error analysis and implementation.

This is joint work with Victor Dominguez and Valery Smyshlyaev.

An asymptotic derived boundary-element method for high-frequency scattering problems in 2D. **Víctor Domínguez** (Universidad Pública de Navarra, Spain), Valery Smyshlyaev (University of Bath, UK), Ivan Graham (University of Bath, UK) IC/MT2120/023

This work concerns itself with the numerical solution of the acoustic scattering of plane waves by smooth convex curves in the high-frequency regime.

The problem is solved by boundary element methods using a direct approach with the normal derivative of the total wave as the new unknown of the problem. The normal derivative is then determined by solving an integral equation on the boundary, the so-called Burton-Miller equation. A complete analysis of the integral equation is developed in the circle where a deep Fourier analysis of the operator is possible. We prove that the condition number of the integral equation increases as $\mathcal{O}(k^{1/3})$, k being the wavenumber, and that the corresponding operator is actually coercive for all k high enough. These results, which have been also observed numerically in 2D, can be straightforwardly extended to spherical obstacles in 3D. As consequence we derive the stability of any Galerkin scheme with the Cea constant growing as $\mathcal{O}(k^{1/3})$.

To devise a method which is robust as the wavenumber k gets large, we use the known asymptotic form of the solution to obtain particular expansions in various zones of the boundary. These expansions allow to write the solution of the integral equation as a product of explicit oscillatory functions and more slowly varying amplitudes in each zone. The discrete spaces used polynomial approximations of the slow amplitude, as therefore can be understood as a sort of p method. In the shadow part a zero approximation is proposed and analytically justified as a good choice when k gets into the high frequency regime.

Our method is almost robust, suffering only from a very weak deterioration as $k \to \infty$ so that a slight increase in the dimension of the discrete space, taking the degrees of freedom as $k^{1/9}$ is a typical behaviour, preserves the accuracy of the numerical solution. Finally, we note that although the matrix of the method is relatively small, each entry is defined by a dou-

ble integral process where the integrand is highly oscillatory. It makes the classical quadrature rules prohibitely expensive to use and therefore different approaches should be considered to compute the integrals. We show some new results on this topic.

An efficient algorithm for high-frequency obstacle scattering in 3D. **Mahadevan Ganesh** (Colorado School of Mines, USA) IC/MT1179/023

We consider a surface integral equation formulation to model high-frequency scattering by a class of three dimensional obstacles. In recent years, there is some good progress in the development, implementation, and analysis of algorithms for high frequency scattering by two dimensional obstacles. However, it is still an open problem to develop corresponding practical algorithms for three dimensional scattering problems. In this work, we propose an efficient approach to simulate high frequency scattered and far fields generated by three dimensional obstacles that can be globally described in spherical coordinates.

Analysis of high-frequency multiple-scattering problems in 3D: the scalar acoustic and the vector electromagnetic equations. **Fatih Ecevit** (Max-Planck-Institut Leipzig, Germany) IC/MT1177/023

Recently developed numerical schemes, based on a combination of asymtotic theory and integral equations, provide very efficient strategies for the solution of high-frequency scattering problems. These methods, however, are strongly dependent on the underlying geometry, and are *mostly* restricted to single-scattering configurations. In this talk, we present a convergence analysis of a multiple-scattering algorithm for a collection of convex obstacles. To begin with, we show that the solution of the multiple-scattering problem can be attained through consideration of an iterative (Neumann) series (that successively accounts for further geometrical wave reflections and) that can be rearranged into a sum over primitive periodic orbits; then we analyze the properties of these periodic orbits in the high-frequency regime. To this end, we begin with a rigorous derivation of asymptotic expansions for the *currents* (i.e. the normal derivative of the fields) on arbitrary orbits, and carrying out a novel analysis of these expansions, we derive *precise analytical formulas* (for the scalar acoustic and vector electromagnetic equations) for the rate of decay of multiple scattering iterates on periodic orbits (of arbitrary period). Finally, we show that the convergence of the multiple-scattering iterates can be significantly improved utilizing these analytical formulas.

IC/MP671/023: Spectral computations for integral operators.

Organiser: Paulo Vasconcelos (Universidade do Porto, Portugal)
Co-organiser: Filomena d'Almeida (Universidade do Porto, Portugal)

Several problems in science and engineering can be modelled by integral operators on function spaces with interest on spectral computations. In this minisymposium we will survey methods for spectral problems dealing with operators defined on infinite dimensional domain and with infinite range. We will see how to approximate those operators by projecting them on finite dimensional subspaces, thus yielding large dimensional matrix spectral problems.

The solution procedures with preconditioning techniques and Krylov or Jacobi–Davidson type subspace methods will also be focused, in order to enlighten this crucial phase and to point out the need for the use of efficient and reliable linear algebra building blocks.

Spectral computations: from operators to matrices. **Filomena d'Almeida** (Universidade do Porto, Portugal), Paulo Vasconcelos (Universidade do Porto, Portugal) IC/MT4510/023

In this presentation we will address the problem of finding spectral values and basis for the corresponding invariant subspaces for bounded operators on Banach spaces. We will make a bridge between the spectral problem for the continuous operator and the computation of the eigenvalues and invariant subspace basis of a matrix. This matrix approximate problem is obtained with a convergent sequence of finite rank continuous operators followed by a restriction of these operators to a finite dimensional subspace. Subsequent defect correction procedures to refine the approximate solutions will also be addressed.

Building and solving matrix eigenproblems. **Mario Ahues** (Université Saint-Etienne, France) IC/MT1511/023

When infinite dimensional spectral problems are approximated through finite rank operator problems or slight perturbations of them, a matrix eigenproblem must be built and solved to compute eigenvalues and corresponding maximal invariant subspaces and eigenspaces.
This contribution covers
- A general theoretical framework for matrix problems issued from finite rank discretizations and perturbed variants,
- The stop criterion of the widely used QR method for the numerical computation of eigenvalues,
- The use of Newton-like methods to refine coarse approximate bases of maximal invariant subspaces in some special cases,
- The possibilities of using the Newton method to compute a Schur form of a complex square matrix as an alternative to the QR algorithm.

Comparison of parallel eigensolvers for a discretized radiative transfer problem. **Osni Marques** (Lawrence Berkeley National Laboratory, USA), Paulo Vasconcelos (Universidade do Porto, Portugal) IC/MT2510/023

In this work we consider the numerical computation of eigenelements of integral operators associated to a radiative transfer problem. This problem models the emission of photons in stellar atmospheres, and is formulated in terms of a weakly singular Fredholm integral equation defined on a Banach space. Computational approaches using direct and iterative strategies available in open source packages are discussed.

Computational challenges and algorithms in electronic structure calculations. **Yousef Saad** (University of Minnesota, USA) IC/MT3627/023

Density Functional Theory (DFT) is a successful technique used to determine the electronic structure of matter which is based on a number of approximations. It converts the original n-particle problem into an effective one-electron system, resulting in a coupled one-electron Schrödinger equation and a Poisson's equation. This coupling, which is nonlinear, involves the charge density which can be computed from the wavefunctions for all occupied states. These wavefunctions in turn are eigenfunctions of a Hamiltonian which depends (nonlinearly) on the charge density. This gives rise to a non-linear eigenvalue problem which is solved iteratively. The challenge comes from the large number of eigenfunctions to be computed for realistic systems with, say, hundreds or thousands of particles. We will discuss a parallel implementation of a finite difference approach for this problem and report on some results. The emphasis will be on solving the large eigenvalue problem. We will also explore the fundamental underlying linear algebra which can be viewed as a problem of determining the diagonal of a projector associated with an invariant subspace. Methods that avoid completely the computation of eigenvectors will be briefly discussed. Finally, we will present algorithms in time-dependent density functional theory with an emphasis on showing some of the resulting big challenges in matrix computation.

IC/MP118/024: The numerical solution of differential equations: recent advances.

Organiser: Paul Muir (Saint Mary's University, Canada)
Co-organiser: Raymond Spiteri (University of Saskatchewan, Canada)

The last few decades have seen a dramatic rise in the use of computational modelling as the primary tool for studying problems in applied and industrial mathematics. It is often the case that the underlying mathematical model is based on a system of differential equations. Increasingly however these models are more naturally formulated as differential–algebraic equations, i.e., differential equations augmented with algebraic equations that must also be satisfied. Applications experts who wish to perform computer simulations with these models continually attempt to study ever more sophisticated models that persistently push the limit of what can be handled with traditional numerical algorithms. Thus there is an ongoing need for the development of new computational techniques for the efficient, accurate, and robust simulation of such models. This mini-symposium brings together researchers who will discuss recent leading-edge advances in the algorithms and software for the numerical solution of differential equations. Topics include the numerical solution of boundary value differential equations with delay and advance terms, error estimation schemes for ODEs and DAEs, aspects of software development for systems of differential–algebraic equations, and a new class of waveform relaxation algorithms for large systems of ODEs arising from discretizations of partial differential equations.

Global a-posteriori *error estimates for index-1 DAEs.* **Ewa Weinmüller** (TU Wien, Austria), Winfried Auzinger (TU Wien, Austria), Herbert Lehner (TU Wien, Austria) IC/MT2675/024

We apply polynomial collocation to approximate solutions to index-1 DAEs in the form

$$A(t)\big(D(t)\,x(t)\big)' + B(t)\,x(t) = g(t)\,, \quad \text{for } t \in [0,1]\,,$$

where $A(t) \in \mathbb{R}^{m\times n}$, $D(t) \in \mathbb{R}^{n\times m}$, $B(t) \in \mathbb{R}^{m\times m}$, $g(t), x(t) \in \mathbb{R}^m$, with $n \le m$. For the numerical solution of the above system, we apply polynomial collocation to the enlarged system:

$$A(t)\,u'(t) + B(t)\,x(t) = g(t)\,, \qquad D(t)\,x(t) - u(t) = 0\,, \quad \text{for } t \in [0,1]\,.$$

Here, we focus on DAEs with so-called *properly stated leading term*, and use a Defect Correction principle to derive a posteriori error estimates for the global discretization error of the collocation scheme. Our procedure generalizes similar techniques which have proved useful in the ODE setting. The main idea of the error estimation procedure is to compute an appropriate defect measuring the quality of the collocation solution, and to apply a low-effort auxiliary scheme (backward Euler) with the defect as an additional inhomogeneous term. This leads the construction of an asymptotically optimal error estimate. In this procedure, local quadrature means of the continuous, pointwise defect of the collocation polynomial are used. We demonstrate that this strategy results in an asymptotically correct error estimate provided the problem data are appropriately smooth, and we illustrate the performance of our strategy by numerical experiments.

Some software aspects of DAEs and optimization software. **Stephen Campbell** (North Carolina State University, USA) IC/MT3676/024

Direct transcription methods have been successfully used to solve a variety of optimal control problems for some time. They are used in a number of codes such as the SOCS software developed at Boeing. In recent years it has begun to be realized that the existing computational theory needs to be modified when talking about direct transcription methods and the solution of constrained optimal control problems where DAEs arise. In addtion some modifications of the existing approach may be necessary if the approach is going to be extended to an even wider class of problems in order to encompass more applications. In this talk we will present two illustrations from our current investigations. Two examples are: use of the theory for constrained differential equations and DAEs and their implications for advice to users, and estimation of adjoint variables.

Algorithms for advanced–retarded differential equation boundary value problems. **Antony Humphries** (McGill University, Canada) IC/MT3345/024

Advanced–Retarded Functional Differential Equations arise in a wide range of applications, recently receiving attention because travelling wave solutions to lattice differential equations are defined by FDE boundary value problems on an unbounded domain. For example, the spatially discrete Nagumo equation

$$\dot{u}_i = u_{i+1} - 2u_i + u_{i-1} - \beta u_i(u_i - a)(u_i - 1), \quad i \in \mathbb{Z}$$

admits travelling waves of the form $u_i(t) = \varphi(i - ct)$ where the waveform $\varphi : \mathbb{R} \to \mathbb{R}$ and wavespeed c satisfy

$$-c\varphi'(\xi) = \varphi(\xi+1) - 2\varphi(\xi) + \varphi(\xi-1) - \beta\varphi(\xi)(\varphi(\xi) - a)(\varphi(\xi) - 1),$$
$$\varphi(-\infty) = 0, \varphi(+\infty) = 1.$$

The presence of advances as well as delays complicates the analysis and numerics of these problems, with the corresponding IVP being ill-posed. Also, the phenomenon of propagation failure, where a standing rather than travelling wave is observed, is represented by a singular limit in the FDE. Two numerical approaches for solving such problems will be presented, firstly by directly solving the BVP using a suitable collocation method, and secondly by using a travelling coordinate embedding. The truncation of the problem to a finite computational domain including the definition of suitable suitable implicit boundary functions, and validation of the algorithms will be discussed. Travelling waves in the spatially discrete Nagumo equation illustrate the issues that arise.

Optimized Schwarz-waveform relaxation algorithms for advection-diffusion problems. **Martin Gander** (Université de Genève, Switzerland) IC/MT4273/024

Optimized Schwarz waveform relaxation algorithms are a new class of waveform relaxation algorithms for large systems of ordinary differential equations (ODEs) arising from discretizations of partial differential equations. Like for classical waveform relaxation algorithms, the system of ODEs is decoupled into subsystems, but then coupling conditions adapted to the physics of the underlying problem are used to re-couple the subsystems with an iterative process. For discretized advection diffusion problems, I will show how to determine the best coupling conditions in two classes of simple coupling conditions, and prove that the new algorithms are well posed and convergent, with a much better convergence rate than the one of the classical waveform relaxation algorithm. I will illustrate the analysis with numerical experiments.

IC/MP3861/024: Taylor-model methods and interval methods: applications.

Organiser: Markus Neher (Universität Karlsruhe (TH), Germany)

Interval arithmetic has been widely used in enclosure methods for almost 40 years. Today, it is a well established tool for the calculation of rigorous error bounds for many problems in numerical analysis. Interest in interval arithmetic has been primarily aroused by the limitations of the floating point number format used on digital computers. Interval arithmetic provides a tool for controlling roundoff errors automatically, by enclosing real numbers into intervals with machine representable bounds and performing interval arithmetic operations with directed outward rounding, such that the exact result of any arithmetic operation is automatically enclosed in a floating point interval, including roundoff errors. Interval analysis is also used for bounding all kinds of truncation errors: the truncation error of an infinite iteration, as in the interval version of Newton's method, the remainder term of a convergent series, discretization errors in the numerical solution of differential equations, etc.

Unfortunately, the utility of interval arithmetic is sometimes impaired by the dependency problem and the wrapping effect, which both can cause overestimation of the solution set of a given problem, such that the computed error bounds may become over-pessimistic in practical calculations. The dependency problem is the lack of interval arithmetic to identify different occurrences of the same variable. For example, $x - x = 0$ holds for each $x \in R$, but $X - X$ is evaluated as $\{x - y \mid x, y \in X\}$. This set includes nonzero numbers, if X is a real interval that contains two or more distinct numbers. The wrapping effect appears when overestimation is enforced by the enclosure of intermediate results into intervals.

To reduce overestimation, Taylor models have been developed as a symbiosis of a computer algebra method and interval arithmetic by M. Berz and his group since the 1990s. A Taylor model of a function f on some interval X consists of the Taylor polynomial p_n of order n of f and an interval remainder term I_n, which encloses the approximation error $|f - p_n|$ on X. In computations that involve f, the function is then replaced by $p_n + I_n$. The polynomial part is propagated by symbolic calculations, whereas the interval remainder term encloses all truncation and roundoff errors that appear in the computation. Software implementations of Taylor models have been applied to a variety of problems, such as global optimization problems, validated multidimensional integration, or the solution of ODEs and DAEs.

The minisymposium deals with the presentation and discussion of recent advances in Taylor model methods and interval methods for various applications.

Interval techniques for enclosures of regions of reachability and controllability and for guaranteed state and parameter estimation of dynamical systems. **Andreas Rauh** (Universität Ulm, Germany), Marco Kletting (Universität Ulm, Germany), Eberhard Hofer (Universität Ulm, Germany) IC/MT1968/024

In this presentation, interval techniques for calculation of outer and inner enclosures of regions of reachability and controllability of dynamical systems are presented. Both discrete-time and continuous-time systems are considered. The applied methods are capable of calculating state enclosures for systems with uncertain parameters, nonlinearities, and time-varying characteristics under the assumption of a predefined finite time horizon. Although both uncertain system parameters and bounded control variables are assumed to be represented by intervals, they have to be distinguished in reachability and controllability analysis. Both reachability and controllability of states must be proven for all possible parameter values but for at least one admissible control sequence. Typically, robustness specifications for controllers of dynamical systems are given in terms of bounds on the system's time response which must not be violated for any possible operating condition.

Robust control strategies for nonlinear systems usually rely on knowledge of all current states. However, the complete state vector is not always directly accessible for measurement. Then, observers are applicable to reconstruct state variables which are not measurable. Additionally, observers are used successfully to improve the measured information by recursive computation of estimates and fusion of information determined by different measurement devices. If guaranteed bounds of all uncertain parameters of a dynamical system (including sensor characteristics) and conservative bounds of all disturbances can be specified, the presented interval observer can provide guaranteed enclosures of all reachable states.

In combination with the above-mentioned techniques for calculation of interval enclosures of regions of controllability and reachability, a mathematical proof of admissibility and robustness of control strategies under consideration of the influence of state estimation techniques becomes possible.

Extensions of ValEncIA-IVP for reduction of over-estimation, for simulation of differential algebraic systems, and for dynamical optimization. **Andreas Rauh** (Universität Ulm, Germany), Ekaterina Auer (Universität Duisburg-Essen, Germany), Johanna Minisini (Universität Ulm, Germany), Eberhard Hofer (Universität Ulm, Germany) IC/MT1964/024

In this presentation, we first summarize the basic routines of the validated solver ValEncIA-IVP (VALidation of state ENClosures using Interval Arithmetic for Initial Value Problems, http://www.valencia-ivp.com/). ValEncIA-IVP computes interval enclosures of all reachable states of dynamical systems described by ordinary differential equations with both uncertain parameters and uncertain initial conditions. These enclosures consist of an arbitrary non-validated approximate solution and additive guaranteed error bounds which are determined by a fixed-point iteration.

Extensions which aim at the reduction of overestimation are necessary for the application of ValEncIA-IVP to high-dimensional real-world systems. Here, tight state enclosures for a sufficiently long time span are desired. However, the main drawback of most methods for overestimation reduction is an increase of the required computational effort. That is, an appropriate compromise between effort and simulation quality is necessary.

The first extension of ValEncIA-IVP is a consistency test eliminating subintervals of *a priori* enclosures computed by the basic version of this solver which originate from overestimation. The second is a new approach for tightening of the enclosures with the help of exponential terms, which prevents growth of the diameters of the computed state enclosures especially for simulation of asymptotically stable systems. Third, we demonstrate implicit integration techniques which can be applied in the consistency test for further reduction of overestimation.

Based on these algorithmic improvements, we develop a first approach to extend ValEncIA-IVP to the simulation of sets of differential algebraic equations. We conclude this presentation with an outlook on the integration of ValEncIA-IVP in an interval arithmetic algorithm for computation of optimal and robust control strategies for uncertain continuous-time processes.

Validated simulation of kinematics and dynamics of multibody systems using interval and Taylor-model-based methods. **Ekaterina Auer** (Universität Duisburg–Essen, Germany) IC/MT1153/024

During the last decades, computer assisted modeling and simulation of multibody systems gained in importance. Computers help to reduce the design and development time for new products and to substitute low cost "virtual" tests for expensive experiments on real life prototypes. Besides, various types of modeling software have found a market in industry owing to their ability to generate models from systems' descriptions automatically. However, the results are often unreliable due to either errors that are unavoidably generated by numerical solvers of differential (or algebraic) systems or inaccuracy induced by the idealization of the model itself. This fact forces developers of modeling software to look for more reliable options, one of which is the use of validated arithmetics and algorithms. The main reasons for choosing a validated approach are, first, the guaranteed correctness of results and, second, the ability to allow for uncertainty in parameters, which helps to provide more realistic models or take into account measurement errors.

In this talk, we would like to present an integrated environment for validated modeling and simulation of kinematics and dynamics of various classes of multibody systems SMARTMOBILE (**S**imulation and **M**odeling of dyn**A**mics in MOBILE: **R**eliable and **T**emplate-based) based on the non-validated tool MOBILE. We will discuss general approaches to validate the behavior of a mechanical system using an integrated environment, the design requirements for a validated modeling and simulation tool, the application of interval and Taylor model based methods to it, as well as our achievements and open problems. We will demonstrate the functionality of the new tool and the importance of application of validated techniques using a variety of toy and close-to-life examples.

An efficient distance algorithm for interval-based octrees with time–space coherence utilization. **Cornelius Grimm** (Universität Duisburg–Essen, Germany), Eva Dyllong (Universität Duisburg–Essen, Germany) IC/MT3924/024

Among other approaches, such as implicit surfaces, constructive solid geometry or boundary representations, octrees feature a powerful technique for the geometric modeling of an object. Three dimensional interval vectors are used to describe the nodes of the octree for a reliable and efficient realization of the hierarchical data structure.

In this paper, a new distance algorithm for rotated and translated octrees is presented. It is based on accurate algorithms that have been shown in [DyllLuth04,DyllLuth06], but involves interval arithmetic for reliable handling of rounding errors. Furthermore, time-space coherence is utilized to increase the efficency of sequential distance calculations: Additional 'color' information is attached to the octree nodes to speed up the distance calculation after a movement of the considered octrees.

Verified high-order optimal control in space-flight dynamics. **Roberto Armellin** (Politecnico di Milano, Italy), Pierluigi Di Lizia (Politecnico di Milano, Italy), Martin Berz (Michigan State University, USA) IC/MT2954/024

Space trajectory design always requires the solution of an optimal control problem in order to maximize the payload launch-mass ratio while achieving the primary mission goals. A certain level of approximation always characterizes the dynamical models adopted to perform the design process. Furthermore the state identification is usually affected by navigation errors. Thus, after the nominal optimal solution has been computed, a control strategy that assures the satisfaction of mission goals in the real scenario must be implemented. Traditional methods consist in non-optimal strategies mainly based on tracking the optimal solution, whereas the effectiveness of the synthesized control law is assessed by expensive Monte Carlo simulations.

In this frame Differential Algebra techniques are proposed as an effective alternative tool to design the control law, whereas Taylor models are subsequently applied to gain a validated controlled solution. By using Differential Algebra the final state dependency on initial conditions, environmental and control parameters is represented by high order Taylor Series expansions. The mission constraints and optimality conditions can then be resolved to higher order using a so-called high order partial inversion of the polynomial relationship for every admissible uncertainty. The control strategy is eventually reduced to a simple function evaluation. The flow of the resulting controlled dynamics is then computed using the verified integrator COSY-VI and a validated enclosure of the solution is obtained. As a result no further analysis on the effect of the uncertainties is required and the use of Monte Carlo simulations is avoided.

The performances of the proposed methods have been assessed by several examples of space mission trajectory design including an Earth-Mars low-thrust interplanetary transfer, a continuous propelled lunar landing trajectory, and an aerocapture maneuver at Mars.

Rigorous global optimization of multiple gravity-assist space trajectories. **Pierluigi Di Lizia** (Politecnico di Milano, Italy), Roberto Armellin (Politecnico di Milano, Italy), Martin Berz (Michigan State University, USA) IC/MT3036/024

Fuel efficient transfer from Earth to outer planets is often performed by means of multiple gravity assists, i.e. the close passing in the vicinity of one or more intermediate planets. The gravitational pull of the moving bodies can be used to increase velocity of the spacecraft and suitably alter its direction. The resulting problem is a constrained global optimization problem, where launch and transfer times between each of the assist planets are the free variables, and constraints are imposed in terms of the Lambert problem due to the necessity to connect two subsequent planets by a Keplerian conic arc.

In the last two decades, space trajectory designers have exploited the benefits of approaching the complex multiple gravity assist interplanetary transfer problem from a global optimisation standpoint. Nowadays, the aim of the trajectory design is not only to find a solution, but also to find the best solution in terms of propellant consumption, while still achieving the mission goals. Unfortunately, the multiple gravity assist interplanetary transfer problem is characterized by an objective function having a large number of clustered minima prevalently due to the complex relative motion of the planets involved in the transfer. This causes local optimisation gradient-based methods to converge to one of this local minimum. Consequently global optimization algorithms should be used.

Taylor model-based global optimization techniques are applied to determine rigorous global optima of the orbits over certain ranges of launch times and arrival times. The problem is practically complicated due to the abundance of local minima, a noticeable dependency problem since times allocated for one planet-connecting arc will influence subsequent maneuvers, and the relatively high dimensionality of the problem.

The performances of the proposed methods are assessed by means of classical multiple gravity assist interplanetary transfer test problems.

Implementing Taylor-model arithmetic with floating-point arithmetic. **Nathalie Revol** (École Normale Supérieure de Lyon, France) IC/MT2423/024

The implementation of Taylor models arithmetic may use floating-point arithmetic to benefit from the speed of the floating-point implementation. The issue is then to take into account the roundoff errors and to add them to the interval remainder. This ensures that the containment property is preserved. Here, we assume that the floating-point arithmetic is compliant with the IEEE-754 standard.

We show how to get tight bounds of the roundoff errors. The first operations we consider are the addition of two Taylor models or the product of a Taylor model by a scalar. Getting exactly the roundoff error of one single addition or multiplication involves the use of the TwoSum and TwoMult algorithms by Dekker and Veltkamp. These errors can be added together to the interval remainder. Various accurate summation algorithms have been developed, such as the one proposed by Rump, Ogita and Oishi. When two Taylor models are multiplied, each coefficient of the product is obtained via a dot product, which can again be computed accurately. The roundoff error for this dot product is thus tight.

Using these accurate techniques, we propose algorithms for the arithmetic operations on Taylor models. We then suggest to use polynomials of best approximation for the elementary functions, at least for the first approximations of low degrees.

Automatic strategies to evaluate formulas on Taylor models and generate proofs in PVS. **Francisco Cháves** (École Normale Supérieure de Lyon, France), Nathalie Revol (École Normale Supérieure de Lyon, France), Marc Daumas (Université de Perpignan, France), César Muñoz (National Institute of Aerospace, USA) IC/MT1724/024

Interval arithmetic [Moore 1966, Neumaier 1990, Jaulin *et al.* 2001] has been used in the last decades with successful results in science, mathematics and engineering. However, dependencies during the evaluation of formulas lead to overestimations of the returned results. Taylor Models have emerged as a convenient way to reduce this effect [Makino and Berz 2003]. They have also been used to solve initial value problems for ordinary differential equations as they provide a native guaranteed integration operator.

Interval Arithmetic as well as Taylor Models may be used to produce proofs as they yield enclosures of mathematical results. As more and more software is used to control devices that should never fail (for example software used for public transportation, medical care or weapons...), certification is now integrated with automated development tools such as the B toolkit or proof checking environment such as PVS [Owre *et al.* 1992].

We continued the development of our library of Taylor Models in PVS [Cháves and Daumas 2006] and we implemented the arctangent as needed to validate its polynomial approximation for example in KB3D or CRLIBM. We decided to work on the arctangent as it is clearly a full fledged example [Lester 2004] for the implementation of a new analytical operator to Taylor Model data type. Working with an automatic proof checker leads to the formalization of Taylor Models, i.e., the creation of a new data type and its operations along with proofs of correctness. Our library relies on PVS interval arithmetic library and strategies [Daumas, Melquiond and Muñoz 2005].

To offer *invisible formal methods* to users [Tiwari *et al.* 2003] we provide new strategies to recursively apply operators on Taylor Models, with as few intervention of the user as possible. With these strategies, users can quickly evaluate a formula and translate it into a fully qualified proof certified by PVS.

IC/MP95/024: Taylor-model methods and interval methods: techniques.

Organiser: Kyoko Makino (Michigan State University, USA)
Co-organiser: Markus Neher (Universität Karlsruhe (TH), Germany)

Interval arithmetic has been widely used in enclosure methods for almost 40 years. Today, it is a well established tool for the calculation of rigorous error bounds for many problems in numerical analysis. Interest in interval arithmetic has been primarily aroused by the limitations of the floating point number format used on digital computers. Interval arithmetic provides a tool for controlling roundoff errors automatically, by enclosing real numbers into intervals with machine representable bounds and performing interval arithmetic operations with directed outward rounding, such that the exact result of any arithmetic operation is automatically enclosed in a floating point interval, including roundoff errors. Interval analysis is also used for bounding all kinds of truncation errors: the truncation error of an infinite iteration, as in the interval version of Newton's method, the remainder term of a convergent series, discretization errors in the numerical solution of differential equations, etc.

Unfortunately, the utility of interval arithmetic is sometimes impaired by the dependency problem and the wrapping effect, which both can cause overestimation of the solution set of a given problem, such that the computed error bounds may become over-pessimistic in practical calculations. The dependency problem is the lack of interval arithmetic to identify different occurrences of the same variable. For example, $x - x = 0$ holds for each real number x, but $X - X$ is evaluated as $\{x - y \mid x, y \in X\}$. This set includes nonzero numbers, if X is a real interval that contains two or more distinct numbers.

The wrapping effect appears when overestimation is enforced by the enclosure of intermediate results into intervals.

To reduce overestimation, Taylor models have been developed as a symbiosis of a computer algebra method and interval arithmetic by M. Berz and his group since the 1990s. A Taylor model of a function f on some interval X consists of the Taylor polynomial p_n of order n of f and an interval remainder term I_n, which encloses the approximation error $|f-p_n|$ on X. In computations that involve f, the function is then replaced by $p_n + I_n$. The polynomial part is propagated by symbolic calculations, whereas the interval remainder term encloses all truncation and roundoff errors that appear in the computation. Software implementations of Taylor models have been applied to a variety of problems, such as global optimization problems, validated multidimensional integration, or the solution of ODEs and DAEs.

The minisymposium deals with the presentation and discussion of recent advances in Taylor model methods and interval methods for various applications.

Introduction to Taylor-model methods. **Markus Neher** (Universität Karlsruhe (TH), Germany) IC/MT1714/024

Interval arithmetic is used in enclosure methods for the calculation of rigorous error bounds for many problems in numerical analysis, such as truncation errors of infinite iterations or discretization errors in the numerical solution of differential equations. Interval arithmetic also provides a tool for controlling roundoff errors in computations with floating point numbers on digital computers automatically, by enclosing real numbers into intervals with machine representable bounds and performing interval arithmetic operations with directed outward rounding, so that the exact result of any arithmetic operation is automatically enclosed in a floating point interval, including roundoff errors.

Unfortunately, the utility of interval arithmetic is sometimes impaired by the dependency problem and the wrapping effect, which both can cause overestimation of the solution set of a given problem, such that the computed error bounds may become over-pessimistic in practical calculations. To reduce overestimation, Taylor models have been developed as a symbiosis of a computer algebra method and interval arithmetic by M. Berz and his group since the 1990s. A Taylor model of a function f on some interval X consists of the Taylor polynomial p_n of order n of f and an interval remainder term I_n, which encloses the approximation error $|f-p_n|$ on X. In computations that involve f, the function is then replaced by $p_n + I_n$. The polynomial part is propagated by symbolic calculations, whereas the interval remainder term encloses all truncation and roundoff errors that appear in the computation. Software implementations of Taylor models have been applied to a variety of problems, such as global optimization problems, validated multidimensional integration, or the solution of ODEs and DAEs.

Our presentation opens a minisymposium on interval methods and Taylor model methods. After an introduction to the basic concepts, we review interval methods and Taylor model methods for various applications.

Efficient Taylor-model-based verified ODE and flow integration using differential-algebraic methods. **Martin Berz** (Michigan State University, USA), Kyoko Makino (Michigan State University, USA) IC/MT3148/024

First we review various methods to provide verified enclosures of the flow of ODEs with a particular emphasis on efficiency. Then we analyze a new method based on establishing the defect of an approximation of the flow by its Taylor polynomial of order n in time and order k in initial conditions, and verified integration of this defect using Taylor model methods.

As is commonly done, first the Taylor time expansion of the center point of the domain of interest is determined as in conventional Taylor integrators. In the second step, the ODE is transformed to relative coordinates around the thus obtained center solution. By using Taylor model arithmetic, a representation of the ODE in these relative coordinates is obtained directly to high order.

In the third step, the Taylor representation of the flow of this ODE is obtained from the Taylor representation of the ODE in relative coordinates using differential algebraic methods, in particular a truncation of the exponential series of the Lie derivative of the flow. Again this step is directly possible using Taylor model arithmetic. For efficiency, it is most important that this step does not require any additional evaluations of the right hand side.

In the final step, an additional transformation to relative coordinates is performed, this time around the flow obtained in the third step. The resulting ODE, when evaluated in Taylor model arithmetic, consists of a vanishing polynomial part and a very small remainder bound. This resulting ODE can be trivially verified by a slope argument.

A comparison with the conventional TM-based verified integration algorithm is performed, showing the merits of the new approach for various problems. Some applications of the method will be presented.

Taylor-model-based enclosure of invariant manifolds for planar diffeomorphisms and applications. **Johannes Grote** (Michigan State University, USA), Martin Berz (Michigan State University, USA), Kyoko Makino (Michigan State University, USA) IC/MT3157/024

Fundamental questions in the study of interesting dynamics of planar diffeomorphisms like the Henon map involve homoclinic phenomena, topological entropy and strange attractors. Inherently, answering these questions requires knowledge about the stable and unstable manifolds, which in the typical case in the plane are smooth curves. We present a method that combines Taylor Model arithmetic with normal-form-transformation based techniques to find highly accurate Taylor Model enclosures of the invariant curves near hyperbolic fixed points. Successive iteration of these local manifold enclosures yields similarly accurate enclosures of significant pieces of the global invariant manifolds. Applications presented include the automatic computation of rigorous accurate enclosures of all homoclinic points in the manifold tangle up to finite iterates. Examples for cases with several thousand homoclinic points are given. This enables us to find symbolic dynamics in the underlying system and consequently compute rigorous lower bounds for its topological entropy.

Analysis of the blunting anti-wrapping strategy. **Kenneth Jackson** (University of Toronto, Canada), Markus Neher (Universität Karlsruhe (TH), Germany), Ned Nedialkov (McMaster University, Canada) IC/MT2744/024

Berz and Makino proposed the *blunting method* for reducing the wrapping-effect in their Taylor-model method for the validated numerical solution of initial-value problems for ordinary differential equations. The blunting method can be viewed as a combination of the well-known parallelepiped and QR-factorization methods for reducing the wrapping effect. We analyze the blunting method and show that, over sufficiently long integration intervals, it behaves like the QR-factorization method.

Reliable safety analysis with continuous-time models. **Mark Stadtherr** (University of Notre Dame, USA), Youdong Lin (University of Notre Dame, USA) IC/MT2026/024

Safe operation has always been a key goal in the design and control of modern technological systems. Quantitative, model-based tools for safety analysis are a relatively recent development and, because of the computational challenges involved, have often been restricted to situations that can be described by fairly simple models. A further challenge is dealing with model uncertainty, indicating possible discrepancies between the mathematical model and the physical system whose safety is being studied.

Generally, a system may be considered unsafe when, under influence of external disturbances or equipment failure, it can reach certain undesirable states. In other words, from a given set of possible initial conditions and inputs and a finite time horizon, the goal is to determine the parts of this set for which safe operation can be guaranteed at all times. This problem has been addressed for some simple discrete time models [1,2]. In this study, we will use more realistic continuous-time models with uncertain parameters to represent the processes under consideration. Uncertain parameters are treated as intervals instead of probability distributions since safety analysis is concerned with the possibility for hazards to occur rather than with their likelihood. A validating parametric ODE solver, VSPODE [3], employing interval and Taylor model methods, will be used to simulate and bound trajectories in the interval-valued dynamic model. In this way, we are able to devise an approach for identifying the regions of operation that are guaranteed to be safe. Examples are used to demonstrate the potential of this approach for reliable safety analysis.

High-order box rejection and pruning for global optimization based on Taylor-model methods. **Kyoko Makino** (Michigan State University, USA), Martin Berz (Michigan State University, USA) IC/MT3161/024

We develop two independent methods that allow box rejection and pruning for rigorous global optimization. Both methods are applicable for the use with Taylor model methods, which allow high-order dependency reduced relaxations of the optimization problem at hand.

The first method is applicable to convex functional relaxations over convex domains, which is characteristic of the situation near isolated minimizers where box rejection and reduction is often most difficult. It is based on an order-by-order decomposition of a general multivariate polynomial with positive definite quadratic part into a polynomial that is known to be positive definite to order n, and a remainder term of order n+1. As such, box rejection and domain pruning can be performed with an accuracy of order n+1.

The other method is based on a simplified version of the Taylor model based high-order inversion method that allows derivative-based exclusion of boxes in a global optimization setting. The use of Taylor models and the high-order inversion allows to do so with a sharpness that scales with the n-th power of the width of the domain boxes. Various examples for the practical use of the method are given, showing both the behavior for specific test cases and in a verified global optimization setting.

The practical use of the method greatly benefits from a method that allows the efficient calculation of (n-1)st order Taylor models (TM) for the gradient of a function in v variables simultaneously with the calculation of the Taylor model of the original function. The method is based on the well-known fact that the derivative of a Taylor polynomial of a function f equals the Taylor polynomial of the derivative of f to one less order. Thus, the knowledge of the Taylor polynomial coefficients of f to order n allows the direct determination of those of its partials by simple manipulation of the coefficients. To obtain the Taylor models for the gradient, it is hence only necessary to also accumulate v additional remainder bounds for the partials. An arithmetic is introduced that achieves this in a seamless way in parallel to conventional TM arithmetic. In typical cases of dimensions 5 to 20, the increase in computation time compared to a regular TM evaluation of the function alone is less than a factor of two.

A highly-accurate high-order verified method to solve the 3D Poisson equation. **Shashikant Manikonda** (Argonne National Laboratory, USA), Martin Berz (Michigan State University, USA), Kyoko Makino (Michigan State University, USA) IC/MT3120/024

The 3D Laplace and Poisson equations are important PDEs of Physics, describing the phenomenology of electrostatics and magnetostatics. For many practical problems, very precise and verified solutions of this PDE are required; but with conventional finite element or finite difference codes this is difficult to achieve because of the need for an exceedingly fine mesh which leads to often prohibitive CPU time.

We present an alternative approach based on high-order quadrature and a high-order finite element method. Both of the ingredients become possible through the use of Taylor model methods. In this approach we decompose the problem of solving the Poisson equation into the problem of solving the Laplace equation and finding the magnetic field due to an arbitrary source distribution. The underlying theory to find verified solutions to both these problems using Taylor model methods is developed. We then present various examples to demonstrate the accuracy achieved using this approach.

Guaranteed affine bound-functions for smooth functions based on Bernstein and Taylor expansion. **Jürgen Garloff** (HTWG Konstanz, Germany), Andrew Smith (HTWG Konstanz, Germany) IC/MT3842/024

A method for the computation of tight affine lower bound functions for arbitrary sufficiently often differentiable functions is presented. These bound functions may be employed in branch and bound algorithms for constrained global optimization problems, or any other application where linear underestimators or relaxations are used. An affine lower bound function is a simple type of convex underestimator which provides more information than merely the use of bounds on the range of a function. If such functions are used to construct relaxations for a global optimization problem, then sub-problems over boxes can be reduced to linear programming problems, which are easier to solve.

Our approach relies on the use of Bernstein expansion and Taylor expansion. Firstly, a Taylor polynomial approximation for the function over a specified box is computed. An affine lower bound function for the Taylor polynomial is computed by exploiting its expansion into Bernstein polynomials, and the associated coefficients. Interval arithmetic is employed to ensure a rigorous lower bound function. Secondly, the remainder of the Taylor expansion is enclosed in an interval, by using established methods from interval analysis. If a sufficiently high degree Taylor expansion is used in the first stage, then this remainder will be small. Subtracting this interval from the lower bound function for the Taylor polynomial provides the lower bound function for the given function.

Some examples will be presented to illustrate the performance of the algorithm. By altering the degree of the Taylor expansion used, a balance between the tightness of the resulting affine bound function and the speed of computation may be achieved.

IC/MP226/025: Mathematical analysis and numerical simulation for Bose-Einstein condensation.

Organiser: Weizhu Bao (National University of Singapore)
Co-organiser: Hailiang Li (Capital Normal University, PR China)

The experimental realization of Bose-Einstein condensates (BEC) in magnetically trapped atomic gases at ultra-low temperature has spurred great excitement in the atomic physics community and renewed the interest in studying the macroscopic quantum behavior of the atoms. Theoretical predictions of the properties of BEC like the density profile, collective excitations and the formation of quantized vortices can now be compared with experimental data. This dramatic progress on the experimental front has stimulated a wave of activity on both the theoretical and the numerical front. In this minisymposium, the speakers will address recent advancements in the following directions: (a). Mathematical analysis on existence and uniqueness of ground states as well as their asymptotics, stability and dynamical laws; (b). Efficient and accurate numerical methods for computing ground states and dynamics of BEC; (c). Dynamics of quantized vortices in BEC; and (d) Analysis and computation for quantum Boltzmann equation for BEC at finite temperature.

Quantized vortices in BEC and superconductors. **Qiang Du** (Pennsylvania State University, USA) IC/MT4147/025

Quantized vortices is a well-know signature of superfluidity. They have been studied extensively in superfluid Helium, type-II superconductors, Bose Einstein condensates and more recently in Fermi gas. We will discuss some mathematical analysis and numerical simulations of the quantized vortex nucleations in superconductors and Bose-Einstein condensates and discuss their connections and similarities.

Solitary waves in Bose-Einstein condensates with inhomogeneous nonlinearities. **Víctor Pérez-García** (Universidad de Castilla-La Mancha, Spain) IC/MT673/025

In this talk I will present several results on the existence, stability and dynamics of solitons in systems with inhomogeneous nonlinearities like Bose-Einstein condensates with spatially dependent scattering length. I will also present families of exact solutions and discuss several effects relevant for applications which can be obtained from the general theory.

Work done in collaboration with: Vadym Vekslerchik (U. Castilla-La Mancha), Juan Belmonte (U. de Castilla-La Mancha), H. Michinel (U. de Vigo) and P. Torres (U. de Granada)

Bifurcation analysis of Bose-Einstein condensates. **Shih-Feng Shieh** (National Taiwan Normal University) IC/MT1380/025

In this talk, we first prove that the solution curve of ground/positive bound states of a two component Bose-Einstein condensate(BEC)undergoes supercritical pitchfork bifurcations at some finite values of the inter-component scattering length. The ground state solutions bifurcate into two symmetric solutions with respect to some suitable axis on the symmetric domain, when a two-component BEC has equal intra-and inter-component scattering lengths. Second, we propose a Gauss-Seidel-type iteration(GSI)for the computation of energy states of a multi-component BEC. We prove that the GSI method converges locally and linearly to a solution of a nonlinear algebraic eigenvalue problem if and only if the associated minimized energy functional problem has a strictly local minimum. Numerical experience shows that the GSI converges globally within 10 to 20 steps.

A Hermite pseudo-spectral method for solving systems of Gross-Pitaevskii equations. **Rada Maria Weishäupl** (Universität Wien, Austria) IC/MT677/025

We propose and analyze discretization methods for solving finite systems of nonlinearly coupled Schrödinger equations, which arise as asymptotic limit of the three-dimensional Gross-Pitaevskii equation with strongly anisotropic potential. A pseudo-spectral method with Hermite basis functions combined with a Crank-Nicolson type method is introduced. Numerical experiments are presented, including a comparison with an alternative discretization approach.

Dynamics of rotating Bose-Einstein condensates and their efficient and accurate numerical computation. **Weizhu Bao** (National University of Singapore) IC/MT531/025

In this talk, we study the dynamics of rotating Bose-Einstein condensates (BEC) based on the Gross-Pitaevskii equation (GPE) with an angular momentum rotation term and present an efficient and accurate algorithm for numerical simulations. We examine the conservation of the angular momentum expectation and the condensate width and analyze the dynamics of a stationary state with a shift in its center. By formulating the equation in either 2D polar coordinate system or 3D cylindrical coordinate system, the angular momentum rotation term becomes a term with constant coefficients. This allows us

to develop an efficient time-splitting method which is time reversible, unconditionally stable, efficient and accurate for the problem. Moreover, it conserves the position density. We also apply the numerical method to study issues such as the stability of central vortex states and the quantized vortex lattice dynamics in rotating BEC.

This is a joint work with Qiang Du and Yanzhi Zhang.

Time-averaging and mathematical modeling of strongly confined Bose–Einstein condensates. **Florian Méhats** (Université de Rennes 1, France) IC/MT2123/025

This talk deals with a work in collaboration with F. Castella (Univ. Rennes, France) and N. Ben Abdallah (Univ. Toulouse, France).We study the limiting behavior of a nonlinear Schrödinger equation describing a 3 dimensional gas that is strongly confined along one or several directions. The confinement induces fast oscillations in time, that need to be averaged out. We analyze rigourously the convergence of a singularly perturbed equation towards a limiting model involving no oscillation. A key mathematical tool for this analysis is the use of almost periodicity.

Complex continuation for rotating Bose–Einstein condensates. **Cheng-Sheng Chien** (National Chung Hsing University, Taiwan) IC/MT1808/025

We study numerical solutions and trapping potentials of rotating Bose-Einstein condensates from the viewpoint of bifurcations. We show that the rotating BEC in the complex plane is governed by special two-coupled nonlinear Schrödinger equations (NLS) in the real domain. The locations of bifurcations are invariant under the affect of angular momentum. The wave functions of a rotating BEC can be easily obtained whenever the solution manifolds of the two-coupled NLS. We also study the bifurcation behavior when the 3D NLS is reduced to a 2D NLS. Numerical results on both the cylindrical domain and the 2D geometries reported. In particular, the numerical results show how the solutions of a single NLS are affected when an angular momentum is imposed on the equation. Moreover, the existence of the numerical solutions of the BEC depends on the choices of trapping potentials.

Numerical method for computing spin-1 Bose-Einstein condensate ground state. **Fong Yin Lim** (National University of Singapore), Weizhu Bao (National University of Singapore) IC/MT658/025

The imaginary time method and gradient flow with discrete normalization have been widely used to solve the Gross-Pitaevskii equation for single component BEC ground state. However, for spinor condensate with internal degree of freedom, difficulties arise as there are insufficient normalization conditions to normalize the coupled gradient flows at discrete time steps. In this presentation, a normalization condition is introduced for spin-1 condensate, in addition to the two existing conditions: the conservation of total particle numbers and the conservation of magnetization. The third normalization condition is derived from the relationships between the chemical potentials of each spinor components together with a splitting scheme applied to the coupled continuous normalized gradient flows. An efficient numerical method, the backward-forward sine-pseudospectral method (BFSP) that was developed to solve single component BEC ground state, is then extended to compute the ground state of spinor BEC.

IC/MP464/025: Efficient mass-conservative numerical schemes for multiphase and multicomponent flow and transport modelling environmental subsurface systems.

Organiser: Markus Bause (Universität Erlangen–Nürnberg, Germany)
Co-organiser: Florin Adrian Radu (Max-Planck-Institut Leipzig, Germany)

Reliable and efficient simulations of multiphase subsurface flows and contaminant transport phenomena are desirable in hydrological and environmental investigations, in civil and environmental engineering and for industrial oil exploration and production studies. The ability to model and simulate complex flows and reactive transport processes in composite soil formations is important from the point of view of physical realism. In this minisymposium recent developments and latest results in the application of numerical methods that are based on conservative techniques to the complex elliptic and parabolic model equations, also with degeneracy, describing such flows and transport phenomena are presented. In particular, mixed finite element methods including also higher order flux discretizations and finite volume based multipoint flux approximation schemes are considered. Various aspects of their analyses and practical implementation are addressed. The performance properties of the considered schemes are compared. The efficiency and reliability of these methods is illustrated by numerical convergence studies and for real-world subsurface flow and contaminant transport scenarios.

Properties of some locally-conservative numerical methods: application to reservoir simulation. **Runhild Klausen** (Universitetet i Oslo, Norway) IC/MT2107/025

The focus will be on discretization methods which are suited for the pressure equation as part of a multiphase subsurface flow problem. Extra focus will be given to various versions of the multi point flux approximations. Qualities, limitations and strengths of different versions of the methods will be discussed with respect to applications. Relationships to more classical methods like the mixed finite element methods will be shown and gains and losses discussed. In particular we will give a discussion on triangulations vs. quadrilaterals, robustness due to roughness in the grids and permeability, possibilities and effect of symmetry.

The work is done in collaboration with G.T. Eigestad, R. Winther and I. Aavatsmark.

Order of convergence estimates for a MFEM–Euler implicit scheme for a class of double degenerate parabolic equations. **Florin Adrian Radu** (Max-Planck-Institut Leipzig, Germany), Iuliu Sorin Pop (TU Eindhoven, The Netherlands), Peter Knabner (Universität Erlangen–Nürnberg, Germany) IC/MT1515/025

We consider here a class of nonlinear parabolic equations which can degenerate in the sense that the nonlinearity appearing in the time derivative can both vanish or blow up. As typical application we have in mind the Richards' equation, in its form after the Kirchhoff transformation, used for modeling saturated/unsaturated flow in porous media. We discretize in time by a scheme equivalent with Euler implicit and in space by the mixed finite element method (MFEM). Precisely, we use the lowest order Raviart-Thomas elements. Error estimates are presented to prove the convergence of the resulting fully discrete scheme. The advantage of the approach is that the convergence is obtained without any extra regularity assumptions.

The new results presented here extend the analysis done in [1].

Higher-order mixed finite-element approximation of sub-surface water flow. **Markus Bause** (Universität Erlangen–Nürnberg, Germany) IC/MT1950/025

In this talk a higher-order finite element approach to variably saturated subsurface water flow and simultaneous (bio-)reactive multicomponent contaminant transport is considered. Higher order techniques have proved advantageous in the reliable and efficient simulation of biochemically reacting and mixing transport processes, due to their less amount of inherent numerical diffusion. Here, we focus in particular on a formally second-order accurate mixed finite element discretization of the parabolic-elliptic degenerate Richards equation, describing water flow in a variably saturated porous medium, by means of the lowest order Brezzi-Douglas-Marini element (BDM_1) and study the impact of the "improved" flux approximation on the transport processes. A new optimal order error estimate for the BDM_1 mixed discretization of a class of nonlinear problems and of the Richards equation is given. Moreover, the numerical performance properties of the BDM_1 approach are carefully compared to those of a first-order accurate Raviart-Thomas discretization (RT_0) and of a first-order accurate finite volume based multipoint flux approximation (MPFA). All these methods have in common that they are locally mass conservative. The comparison is done for various test cases. Finally, the application of the mixed finite element approach to subsurface water flow, with BDM_1 and RT_0 elements, is illustrated for some realistic complex field scale groundwater contamination scenarios with multicomponent reactive transport.

Entropy solutions of the Buckley–Leverett equation as limit of dynamic capillarity models. **Iuliu Sorin Pop** (TU Eindhoven, The Netherlands), van Duijn Hans (TU Eindhoven, The Netherlands), Peletier Bert (Universiteit Leiden, The Netherlands) IC/MT1565/025

We discuss an extension of the Buckley–Leverett (BL) equation describing two-phase flow in porous media. This extension includes a third order mixed derivatives term and models the dynamic effects in the pressure difference between the two phases. We derive existence conditions for traveling wave solutions of the extended model. This leads to admissible shocks for the original BL equation, which violate the Oleinik entropy condition and are therefore called nonclassical. In this way we obtain non-monotone weak solutions of the initial-boundary value problem for the BL equation consisting of constant states separated by shocks. Such results have been obtained experimentally. We conclude this talk by numerical experiments confirming the theoretical analysis.

IC/MP928/025: New directions in PDE simulations.

Organiser: David Bortz (University of Colorado at Boulder, USA)

Recent developments in numerical PDEs such as grid-free particle methods as well as fast-solver based boundary integral approaches suggest exciting possibilities for dramatic improvement in simulation time as well as physical realism. In some cases, the analysis of these methods do not easily lend themselves to traditional numerical analysis techniques. The purpose of this minisymposium is to showcase both the recent advances in PDE simulation approaches as well as novel approaches in studying the fidelity of the numerical simulation.

Numerical heating and particle codes. **Andrew Christlieb** (Michigan State Univsersity, USA) IC/MT3181/025

Plasmas (ionized gases) have rich and complex behavior which often need multiple lines of attack to fully understand their rich dynamics. Depending on the length scales involved, the plasma may be described by either a kinetic or a fluid model, the kinetic model being the more fundamental of the two. In this talk we will give a brief overview of the relation between these two models and then discuss Lagrangian particle methods for kinetic plasma problems. In particular, we will discuss the issue of numerical heating in a verity of grid-based and grid-free particle methods. This includes issue's of time stepping errors, mesh based effects, particle shape functions (type of regularization) and number of macro-particles. A further source of numerical heating is through the inclusion on inter-particle collisions via a monte-carlo approximation. It has been demonstrated that in 1D, the statistical error couples in a nonlinear way to the long range fields. We will spend the last portion of our talk discussing this issue.

Convergence analysis of grid-free PDE methods. **David Bortz** (University of Colorado at Boulder, USA), Andrew Christlieb (Michigan State Univsersity, USA) IC/MT3246/025

Grid-free numerical methods for solving PDE's have recently received considerable attention in the plasma simulation community. In this talk, we will present preliminary work on a novel framework for analyzing the convergence properties of this class of methods. The main idea of this framework focuses on employing statistical and connectivity properties of discretizations of differential operators to provide an alternative convergence metric.

Rapid evaluation of electrostatic interactions in multi-phase media. **Per-Gunnar Martinsson** (University of Colorado at Boulder, USA) IC/MT3370/025

In this talk, we will describe some fast numerical techniques for solving electro-statics problems involving a number of charged particles in a domain consisting of two or more regions with different dielectric constants. Such problems frequently need to be solved at each timestep in Monte Carlo or molecular dynamics simulations of biochemical phenomena, semi-conductors, etc. Since typically a very large number of problems need to be solved, computational speed is of crucial importance. For this reason, FFT-based solvers operating on equispaced grids have been a method of choice – in spite of a lack of rigorous error control, or the possibility of adaptive mesh refinement. In this talk, we will demonstrate that methods based on integral equation formulations can be as fast as, and sometimes substantially faster, than FFT-based methods. A principal advantage of integral equation based methods is that the discretization points are placed exactly at the locations where the physics is of interest (domain boundaries, charge locations, etc). This makes it possible to simultaneously achieve complete error control and superior computational speed.

Second-order embedded-boundary methods for electromagnetic particle-in-cell. **Matthew Bettencourt** (Air Force Research Lab., Kirtland AFB, USA) IC/MT3826/025

The mainstay of low density plasma simulations has been handled with electromagnetic particle-in-cell codes. These codes typically relied on the Finite-Difference Time-Domain algorithm for the electromagnetics and the Boris push with conservative current weighting by Villasenor and Buneman. These techniques suffer from a loss of accuracy near physical boundaries due to the stair-cased approximation. This talk outlines an approach to solving both the electromagnetics and the particle portions of this problem with cut-cell embedded boundaries, restoring second order accuracy and reducing the error by an order of magnitude.

IC/MP253/025: High-order shock capturing methods for non-linear hyperbolic partial differential equations.

Organiser: Miroslav Čada (ETH Zürich, Switzerland)
Co-organiser: Vincent Wheatley (ETH Zürich, Switzerland)

In recent years, there have been major advances in the design of numerical algorithms for solving non-linear hyperbolic conservation laws. In order to deal with problems involving long time dependency, multiple wave interactions, and discontinuous waves such as shocks and contact discontinuities, a numerical algorithm has to be fast, accurate and, in terms of shocks, non-oscillatory. To resolve the fine-scale features of a solution, turbulence being one example, it is also desirable for the algorithm to be high order accurate and have low numerical dissipation away from discontinuities. This challenge has led to a wide spectrum of possible methods. In general we can characterize three different groups, namely finite volume or finite difference methods, finite element methods and hybrid methods. In order to achieve better spacial resolution, high-order polynomial reconstructions and more recently non-polynomial reconstructions using hyperbolae and logarithmic functions have been used. These are then implemented in the context of finite volume or finite element methods using smoothness indicators to detect the presence of discontinuous waves. Hybrid methods adopt this idea, but try to combine shock capturing methods with, for example, spectral methods or high-order central differences. A major difficulty is the construction of a sophisticated smoothness indicator that can distinguish between smooth but narrow extrema and sharp discontinuities. We hope to explore both the present capabilities and limitations of these methods, along with what advances may be close at hand.

Shock-capturing schemes: high accuracy versus total-variation boundedness. **Antonio Marquina** (Departamento Matematica Aplicada, Universidad de, Spain), Susana Serna (University of California, Los Angeles, USA) IC/MT3758/025

High-order accurate shock capturing schemes are designed to resolve complex shock dynamics with high accuracy in space and time avoiding spurious oscillations near discontinuities. The presence of moving discontinuities in the flow at different scales makes this issue a computational challenge. We review different approaches from Lax-Wendroff and Van Leer pioneering contributions, through Harten total variation diminishing schemes (TVD) and essentially non oscillatory (ENO) piecewise polynomial schemes, to the more recent weighted ENO schemes and piecewise hyperbolic and logarithmic schemes. We discuss the use of slope limiters to reduce the degeneration in accuracy near discontinuities. We present a set of numerical experiments showing advantages and disadvantages of the different approaches.

High-order well-balanced central schems on staggered grids, with application to shallow-water equations. **Giovanni Russo** (Università degli Studi di Catania, Italy), Alexander Khe (Lavrentyev Institute of Hydrodynamics, Russian Federation) IC/MT3848/025

A new family of high resolution shock captiring finite volume schemes is proposed for the numerical solution of systems of balance laws. Space-time discretization is obtained by the Central Runge-Kutta approach [1], previously introduced for the cnstruction of high order central schemes for conservation laws. High order non oscillatory property is obtained by the use of WENO reconstruction in space, and Runge-Kutta in time. The well-balanced property is guaranteed by performing the reconstruction in the so called equilibrium variables, rather than in the conservative of characteristic variables. A suitable map betwenn conservative and equilibrium variables, which preserves conservation, is used. Applications to the shallow water equations are presented. The numerical results illustrate the high order accuracy, and well-balanced property of the scheme, for perturbation around arbitrary equilibria.

Central finite-volume and HLLC-type methods for hyperbolic systems and ideal MHD. **Paul Arminjon Paul** (Université de Montréal, Canada) IC/MT3989/025

Central Finite Volume methods , based on the staggered Lax-Friedrichs and Nessyahu-Tadmor one-dimensional Difference schemes , avoid the resolution of the Riemann problems generated at the cell interfaces thanks to the use of two staggered Grids at alternate time steps . Widely used and tested in applications to transonic/supersonic compressible flows using either Cartesian or Unstructured Triangular/Tetrahedric grids, they provide second-order accurate , computationally efficient and (in conjunction with appropriate limiters) non-oscillatory solvers for nonlinear hyperbolic systems.

We have recently adapted these methods to problems in ideal Magnetohydrodynamics, where we constructed appropriate extensions of Evans and Hawley's Constrained Transport method to satisfy the $\mathrm{div}\, B = 0$ constraint , and showed their feasibil-

ity, accuracy and robustness: even when we do not apply our CTCS divergence treatment to the magnetic field , our results remained meaningful , albeit not as accurate as when we apply this divergence treatment . We are also considering some versions of the HLLC Riemann solver for these problems , and compare the two approaches .

High-order ADER finite-volume schemes for diffusion–reaction equations. **Eleuterio Toro** (Università degli Studi di Torino, Italy) IC/MT4011/025

We construct very-high order finite volume schemes for solving non-linear diffusion-reaction parabolic equations, following the ADER approach, first developed for hyperbolic equations [1]. A key step in the construction of the schemes is an approximation to the solution of a high-order Riemann problem for parabolic equations of the diffusion-reaction type. We note that the obvious generalization of the classical first-order Godunov scheme for diffusion leads to an inconsistent scheme. This difficulty is resolved in a very natural way by considering high-order Riemann problems, or derivative Riemann problems, as for the hyperbolic case [2], [3]. These are Cauchy problems in which the initial conditions are, for example, high-order polynomials in space and the sought solution at the interface is a high-order polynomial in time. The schemes are non-linear, the high-order representation of the polynomial data comes from a modified conservative ENO approach; the modification puts restrictions of the lengths of the stencils, based on accuracy and stability considerations.

Schemes of up to 10th order in space and time are implemented and assessed, with particular attention to the convergence rates of the schemes.

IC/MP840/025: High-order methods for wave propagation and flow problems in complex geometries.

Organiser: Michael Dumbser (Universität Stuttgart, Germany)
Co-organiser: Eleuterio Toro (Università degli Studi di Torino, Italy)
Co-organiser: Claus-Dieter Munz (Universität Stuttgart, Germany)

This Minisymposium is concerned with latest developments on high order accurate numerical methods for constructing linear and non-linear numerical schemes of high order of accuracy in space and time for solving partial differential equations in multiple space dimensions on unstructured grids. The considered schemes are always time-accurate to compute transient phenomena, however, by construction they may easily incorporate local-time stepping to increase computational efficiency. Problems of interest involve wave propagation problems as well as flow and transport phenomena. One lecture will be devoted to provide a brief review of the ADER approach and of the basic ingredients, such as the solution of the Derivative (or Generalized) Riemann problem. Other lectures will address the design of ADER Finite Volume (ADER-FV) and ADER Discontinuous Galerkin (ADER-DG) schemes on unstructured meshes in multiple space dimensions for complicated domains, including high-order non-linear WENO reconstruction procedures on triangular and tetrahedral meshes. The workshop will also include several applications of the numerical methods to typical wave propagation and fluid flow problems that require the use of numerical schemes of high order of accuracy, namely elastic wave propagation in heterogeneous anisotropic viscoelastic material as well as compressible gasdynamics.

Approaches for solving the derivative Riemann problem. **Eleuterio Toro** (Università degli Studi di Torino, Italy) IC/MT4442/025

The Derivative (or higher-order) Riemann problem for non-linear systems of hyperbolic balance laws is the Cauchy problem for the relevant system of equations in which the initial conditions are piece-wise smooth. The motivation of this work is the construction of high-order Godunov type methods for conservations laws, called ADER methods. We present various techniques for obtaining solutions to this problem along time axis, as a time power series expansion. One method, first put forward by Toro and Titarev (2002), is based on a power series expansion of the sought solution at the interface position x=0. The leading term is found by solving a classical Riemann problem (piece-wise constant data) for the state variables and the coefficients of the higher-order terms in the expansion result from solving classical Riemann problems for space derivatives, after using the Cauchy-Kowalewski procedure. Another method of solution due to Castro and Toro (2006) results from a re-interpretation of the higher order method of Harten, Engquist, Osher and Chakravarthy (1987). Here, power series expansions on either side of the initial discontinuity are first written. The Cauchy-Kowalewski procedure allows the use of the initial conditions and the differential equations to define left and right states at any time. There follows the solution of a non-linear classical Riemann problem to find the solution of the higher-order Riemann problem at the given time at x=0. These methods work well for hyperbolic equations with non-stiff source terms. We also discuss a recent alternative method due to Dumbser, Enaux and Toro (2007) where the Cauchy-Kowalewski procedure inside each control volume is replaced by a local space-time discontinuous Galerkin scheme. We emphasize that with this new approach one can still construct non-oscillatory numerical methods of arbitrary order of accuracy in space and time for nonlinear systems of balance laws with source terms that may even be very stiff.

A discontinuous Galerkin scheme based on a space-time expansion. **Claus-Dieter Munz** (Universität Stuttgart, Germany) IC/MT4437/025

The class of discontinuous Galerkin (DG) schemes is interesting for practical calculations of problems in complex geometries, because the approximate solutions usually show the theoretical order of accuracy even on distorted unstructured grids. Due to the fact that the approximate solution in the DG schemes may be discontinuous at grid cell interfaces, they allow the approximation of strong gradients on coarse grids. In this talk we propose a discontinuous Galerkin scheme which is based on a space-time Taylor expansion about the barycenter at the old time level. All time or mixed space-time derivatives

are replaced by pure space derivatives using the evolutionary differential equation several times which is called the Cauchy-Kovalevskaya procedure. The Taylor expansion gives the values for the Gaussian quadrature rules which are applied to the surface and volume space-time integrals in the variational formulation. We discuss the numerical approximation of the advective as well as the diffusive fluxes between the grid cells.

The proposed scheme is used in a way such that it is locally adapted to the behavior of the solution. This includes h-adaptivity, which is especially efficient due to the possibility to have nonconforming mesh nodes, and p-adaptivity allowing the degree of the local approximation space to vary from element to element. The space-time expansion discontinuous Galerkin scheme (STE-DG) scheme is also locally adapted with respect to the time approximation. We have no longer a global time step, but each grid cell may evolve in time with a local time step corresponding to the local stability restrictions. This technique highly increases performance for multi-scale problems where the local time steps strongly vary over the computational domain.

We show an example for a simulation in aeroacoustics in which the noise generating region as well as the propagation of acoustic waves into the far-field are simulated. Another example is the simulation of fluid flow based on the compressible Navier-Stokes equations. The flexibility and adaptivity of the scheme allows to vary the order of the approximation as well as the grid cell size corresponding to local behavior of the solution, while the local time stepping always guarantees efficiency of the simulation on the entire domain.

The co-authors of this paper are Gregor Gassner and Frieder Lörcher

ADER Runge–Kutta methods for conservation laws. **Giovanni Russo** (Università degli Studi di Catania, Italy) IC/MT4484/025

A new family of high resolution finite volume schemes for the numerical approximation of solutions of conservation laws is presented. The schemes are based on a combination of ADER schemes with Central Runge-Kutta time discretization. In original ADER schemes, at the edge of each computational cell the so-called Derivative Riemann problem for the state variable u is posed with the initial left and right states provided by a suitable high order non oscillatory reconstruction, such as WENO. The solution is then given in a form of the Taylor expansion in time whose oefficients are expressed in terms of high order space derivatives, by successive differentiation of the governing equation.

In the new approach, the Taylor expansion in time is replaced by a Runge-Kutta scheme. Using the CRK approach, the conservative numerical solution for the cell average is expressed in terms of the stage values computed at theedge of the cell. The latter in turn are evaluated by a triangular approach: a p-stage scheme requires p-1 values of the space first derivative, computed by the evolution equation for u_x; such values require p-2 values of the second space derivative, and so on.

The overal procedure will provide essentially the same results of the original ADER scheme, but at a lower copmutational cost. Numerical results on one and two space dimensions will be presented.

Quadrature-free WENO finite-volume schemes for nonlinear hyperbolic systems on unstructured triangular and tetrahedral meshes in 2D and 3D. **Michael Dumbser** (Universität Stuttgart, Germany) IC/MT4430/025

In our talk we present a quadrature-free weighted essentially non-oscillatory (WENO) finite volume scheme of arbitrary high order of accuracy both in space and time for solving time-dependent nonlinear hyperbolic systems on unstructured triangular and tetrahedral meshes in two and three space dimensions, respectively. For high order spatial discretization, a WENO reconstruction technique provides the reconstruction polynomials in terms of a hierarchical orthogonal polynomial basis over a reference element. To ensure non-oscillatory behaviour also for nonlinear systems, characteristic reconstruction is used. The Cauchy-Kovalewski procedure applied to the reconstructed data yields for each element a space-time Taylor series for the evolution of the state and the physical fluxes. This Taylor series is then inserted into a new numerical flux which is a function of four arguments, namely the states and the physical fluxes on both sides of the interface, and which can then be subsequently integrated analytically in space and time. Thus, the Cauchy-Kovalewski procedure provides a natural, direct and cost-efficient way to obtain a quadrature-free formulation, avoiding the expensive numerical quadrature arising usually for high order finite volume schemes in three space dimensions. We show numerical convergence results up to sixth order of accuracy in space and time for the compressible Euler equations of gas dynamics on triangular and tetrahedral meshes in two and three space dimensions. Furthermore, various unsteady two- and three-dimensional flow problems with smooth and discontinuous solutions are computed to validate the accuracy of the approach and to underline the non-oscillatory shock-capturing properties of the method. To our knowledge, this is the first high order accurate quadrature-free WENO finite volume scheme ever presented for nonlinear hyperbolic systems on unstructured three-dimensional tetrahedral meshes. As a final outlook to future applications, first results for the compressible unsteady Navier-Stokes equations on unstructured triangular and tetrahedral meshes in two and three space dimensions are shown.

IC/MP32/025: Artificial boundary conditions for linear and nonlinear Schrödinger equations.

Organiser: Matthias Ehrhardt (TU Berlin, Germany)
Co-organiser: Xavier Antoine (Université Henri Poincaré Nancy I, France)
Co-organiser: Christophe Besse (Université Lille 1, France)

We discuss recent developments related to the numerical solution of time-dependent linear and nonlinear Schrödinger equations on unbounded domains. The eight speakers will focus on the three following topics which are of primary interest concerning Schrödinger-type equations:

1) recent approaches to implement the classical *transparent boundary condition* into finite difference and finite element discretizations for the one-dimensional problems;
2) new strategies to derive fast and stable implementations of the convolution operators involved in the definition of the *artificial boundary conditions* (ABCs); and
3) recent construction of ABCs for nonlinear (cubic) Schrödinger equations or/and for general geometries of the computational domain.

When computing numerically the solution of a linear or nonlinear partial differential equation in an unbounded domain, a fictitious boundary is usually introduced to limit the computational domain. Special boundary conditions are derived at this boundary to approximate the exact whole-space solution. If the solution of the problem on the bounded domain is equal to the whole-space solution (restricted to the computational domain) these boundary conditions are called exact or transparent boundary conditions (TBCs), otherwise they are called artificial boundary conditions (ABCs). Different strategies can therefore be developed. In this minisymposium we are planning to invite people who made recent developments on this subject for linear and nonlinear Schrödinger equations; e.g., the cubic Schrödinger equation. An example for a cu-

bic Schrödinger equation arises in nonlinear optics for laser beam propagation where the polarization of the material has a cubic nonlinearity due to the electric field. More applications stem from fiber optics communications, quantum mechanics or plasma physics.

In the case of a linear equation (even in the one-dimensional case), different complex questions must be considered

- How to derive a stable and accurate scheme for approximating the nonlocal convolution operator defining the boundary condition?
- How to build some accurate TBCs or ABCs for two-dimensional problems?
- Since the TBCs and ABCs include a convolution operator in time (and eventually space), with a weakly decaying kernel, its evaluation becomes very costly for long-time simulations. How to derive then some efficient evaluation algorithms for such operators to reduce the complexity?

These questions will be discussed in the first part of the minisymposium and the first talk of the second part.

While TBCs/ABCs for linear equations can be constructed via integral transformations (Laplace-, Fourier-, Z-transformation) the construction of continuous TBCs/ABCs for nonlinear Schrödinger equations is based on pseudo-differential and para-differential techniques and is far from being trivial. This area represents a current and challenging research topic which will be discussed during the second part of this minisymposium.

Construction of 2D artificial boundary conditions for the linear Schrödinger equation via fractional pseudo-differential operators. **Christophe Besse** (Université Lille 1, France), Xavier Antoine (Université Henri Poincaré Nancy I, France) IC/MT1529/002

A transparent boundary condition for the two-dimensional linear Schrödinger equation is constructed through a microlocal approximation of the operator associating the Dirichlet data to the Neumann one in a "M-quasi hyperbolic" region. To be usable, this condition must be approximated in a high-frequency regime by an asymptotic artificial boundary conditions which involves fractional derivatives with respect to the time variable. In such a way, these conditions present the features of being differential in space and non-local in time. Then, we address the construction and study of a Crank-Nicolson-type discretization of the two-dimensional linear Schrödinger equation in a bounded domain Ω with these artificial boundary conditions set on the arbitrarily shaped boundary of Ω. After having proved the well-posedness of the continuous truncated initial boundary value problem, a semi-discrete Crank-Nicolson-type scheme for the bounded problem is introduced and its stability is provided. Next, the full discretization is realized by the way of a standard finite-element method to preserve the stability of the scheme. Some numerical simulations are given to illustrate the effectiveness and flexibility of the developed method.

Exact absorbing boundary conditions for the Schrödinger equation with periodic potentials at infinity. **Chunxiong Zheng** (Tsinghua University, PR China) IC/MT5006/002

In this talk we will present a novel exact absorbing boundary condition for the Schrödinger equation with inversion-symmetric potentials at infinity. This boundary condition, in a form of Dirichlet-to-Neumann mapping, is based on an analytical expression of the logarithmic derivative of the Floquet solution to the Schrödinger equation. We will explain how we derive this expression and discuss the possibility of its extension to the more general case.

Absorbing boundary conditions for one-dimensional nonlinear Schrödinger equations. **Jérémie Szeftel** (Princeton University, USA) IC/MT3382/002

We construct two families of absorbing boundary conditions for the nonlinear Schrödinger equation. The first one relies on the reinterpretation of the nonlinear equation as a linear one with a potential term and the second one relies on the linearization of the equation. We then present numerical experiments illustrating the efficiency of these methods.

Construction and numerical approximation of artificial boundary conditions for a nonlinear Schrödinger equation. **Stéphane Descombes** (Ecole Normale Superieure de Lyon, France), Christophe Besse (Université Lille 1, France), Xavier Antoine (Université Henri Poincaré Nancy I, France) IC/MT2370/002

In this talk we give a construction of nonlinear artificial boundary conditions for the one-dimensional nonlinear cubic Schrödinger equation. Basically, the derivation consists in formally replacing the nonlinearity by a potential and constructing different kinds of approximate artificial boundary conditions for the resulting problem using the techniques of pseudodifferential calculus. Next, the potential is formally replaced by the nonlinearity. Numerical examples illustrate the efficiency of the non-linear artificial boundary conditions.

IC/MP32/025: Artificial boundary conditions for linear and nonlinear Schrödinger equations. #2

Organiser: Matthias Ehrhardt (TU Berlin, Germany)
Co-organiser: Xavier Antoine (Université Henri Poincaré Nancy I, France)
Co-organiser: Christophe Besse (Université Lille 1, France)

(For abstract, see session #1 above.)

A review of transparent and artificial boundary-condition techniques for linear and nonlinear Schrödinger equations. **Matthias Ehrhardt** (TU Berlin, Germany), Xavier Antoine (Université Henri Poincaré Nancy I, France), Anton Arnold (TU Wien, Austria), Christophe Besse (Université Lille 1, France), Achim Schädle (Zuse-Institut Berlin, Germany) IC/MT1425/002

In this review we discuss different techniques to solve numerically the time-dependent Schrödinger equation on unbounded domains. We present and compare several approaches to implement the classical *transparent boundary condition* into finite difference and finite element discretizations. We present in detail the approaches of the authors and describe briefly alternative ideas pointing out the relations between these works. We conclude with several numerical examples from different application areas to compare the presented techniques. Here we mainly focus on the one-dimensional problem.

Construction of stable discretization schemes of the transparent boundary. **Xavier Antoine** (Université Henri Poincaré Nancy I, France) IC/MT455/002

This talk will be devoted to the construction of stable discretization schemes associated with the linear one-dimensional Schrödinger equation. We will describe both the strategy to achieve this goal and a few numerical experiments showing that the method is effective.

WKB-schemes and open boundary conditions for quantum devices. **Anton Arnold** (TU Wien, Austria) IC/MT1609/002

We shall discuss two numerical tools that are crucial for numerical simulations of quantum wave guides in terms of the Schrödinger equation:

Firstly, we consider the stationary Schrödinger equation $-\epsilon^2\psi_{xx} + a(x)\psi = 0$ in both the oscillatory and the evanescant regimes. In the highly oscillatory case we discuss finite difference methods that do *not* require to resolve the oscillations. This can be achieved by a transformation that separates the oscillations from a slowly varying "envelope". In the evanescant regime we use a FEM with WKB ansatz functions of exponential type. Convergence, stability, and efficience of the resulting method are presented.

In the second part of the talk we present inhomogeneous transparent boundary conditions for the time-dependent Schrödinger equation.

Construction of transparent boundary conditions by the pole-condition method. **Frank Schmidt** (Zuse-Institut Berlin, Germany), Achim Schädle (Zuse-Institut Berlin, Germany), Daniel Ruprecht (Zuse-Institut Berlin, Germany), Lin Zschiedrich (Zuse-Institut Berlin, Germany) IC/MT2684/002

We present a general framework to treat the wave equation, the drift-diffusion equation, the heat equation, and the Schrödinger equation

$$\begin{aligned}
\partial_{tt}u(t,x) &= \partial_{xx}u(t,x) - k^2(t,x)u(t,x) \quad \text{(wave)}\\
\partial_t u(t,x) &= \partial_{xx}u(t,x) + 2d\partial_x u(t,x) - k^2(t,x)u(t,x) \quad \text{(drift-diffusion)}\\
i\partial_t u(t,x) &= \partial_{xx}u(t,x) - k^2(t,x)u(t,x) \quad \text{(Schrödinger)}
\end{aligned}$$

for $x \in \mathbb{R}$ and $t \geq 0$ complemented with appropriate initial conditions. The treatment is based on the pole condition concept and yields a general approach to all these different equations. The concept is not restricted to 1D spatial problems but generalizes directly to higher dimensions.

The basic idea of the pole condition approach is to consider the Laplace transform in space of u in the exterior of a bounded computational domain at each point in time. The function u is an outgoing wave with respect to the computational domain, if all poles of the Laplace transform of u are contained in a proper defined half-plane of the complex plane for all times. For the construction of the algorithm we use an indirect form of the pole condition in time. We study the position of the poles in the complex plane in dependence of the frequency of the Fourier transformed (in time) function u and require that all poles are contained in a proper defined half-plane of the complex plane for all positive frequencies. The definition of the half-plane depends on the nature of the equation and can be computed directly. The algorithmic realization of the pole condition yields constraints which become ordinary differential equations (ODEs) in time and which have to be solved together with the partial differential equation of the interior domain. The number of these additional ODEs determines the accuracy of the approximation in the exterior domain. Numerical tests for all equations yield exponential fast and stable convergence.

IC/MP107/025: Recent advances in front propagation modelling and applications.

Organiser: Maurizio Falcone (Universita' di Roma "La Sapienza", Italy)
Co-organiser: Regis Monneau (Ecole Nationale des Ponts et Chaussées, France)

The numerical computation of the evolution of fronts is one of the most challenging problem with a large number of applications. Let us mention for instance the evolutions of free surfaces of fluids, shape optimization, the detection of contours in image processing, crystal growth and dislocations dynamics. In the last few years, there was a lot of progress in the understanding of these problems which has produced new models as well as new approximation schemes. All the above problems correspond to nonlinear evolutive partial differential equations which can be degenerate. Since the solution can develop singularities and the topology of the interface can change in finite time there is a need for highly accurate numerical methods which are stable with respect to those degeneracies. From the mathematical point of view, the notion of *viscosity solution* plays a crucial role to define the interface after the onset of singularities. In order to compute sharp interfaces, several techniques have been developed: adaptive finite elements, high order finite differences and semi-Lagrangian methods.

This minisymposium will focus on the most recent modelling of fronts evolutions and on accurate approximation methods to compute the solution of significant applied problems.

Tracking propagation of self-intersecting fronts: an invariant manifold approach. **Alexander Vladimirsky** (Cornell University, USA) IC/MT3701/025

In many front propagation problems, the front's position at the time t is represented as a particular level set of a solution to the corresponding first-order non-linear PDE. Typically, this PDE does not have a globally smooth solution and a unique (single-valued) viscosity solution is sought to automatically remove emerging self-intersections of the front. However, a smooth multi-valued solution is needed instead whenever the behavior of characteristics is still relevant even after their intersection (e.g., in geometric optics, multiple-arrival seismic imaging, and tomography).

Multi-valued solutions are frequently computed using Lagrangian methods (e.g., ray tracing) – solving the (2n-dimensional system of) characteristic ODEs for a finite number of initial conditions determined by the boundary conditions of the original PDE. The disadvantage of this approach is a poor spatial resolution due to a non-uniform rate of separation for trajectories of the ODE system. A number of Eulerian methods were proposed to alleviate this problem by solving a corresponding Liouville system of n linear PDEs in a 2n-dimensional (x,p) phase space.

We propose an alternative approach, which restricts the computations to an n-dimensional mesh approximating a particular invariant manifold of the characteristic vector field. That manifold is locally modeled as a graph of the function satisfying a quasi-linear flow-invariance PDE, which is then efficiently solved by a space-marching method in Eulerian framework. We illustrate our approach by computing multi-valued solutions for several Hamilton-Jacobi PDEs and hyperbolic conservation laws. This research is conducted in collaboration with J. Guckenheimer and J.A. Sethian.

High-order semi-Lagrangian contouring with complex moving interfaces. **John Strain** (University of California, Berkeley, USA) IC/MT1365/025

Models of physical phenomena such as crystal growth or blood flow generally involve complex moving interfaces, with velocities determined by interfacial geometry and material physics. Numerical methods for such models tend to be customized. As a consequence, they must be redesigned whenever the model changes.

We present a general computational algorithm for evolving complex interfaces which treats the velocity as a black box, thus avoiding model-dependent issues. The interface is implicitly updated via an explicit second-order semi-Lagrangian advection formula which converts moving interfaces to a contouring problem. Spatial and temporal resolutions are decoupled, permitting grid-free adaptive refinement of the interface geometry. A modular implementation computes highly accurate solutions to geometric moving interface problems involving merging, anisotropy, faceting, curvature, dynamic topology and nonlocal interactions.

A large time-step technique for geometric equations. **Roberto Ferretti** (Universita' Roma Tre, Italy), Elisabetta Carlini (Università degli Studi di Roma "La Sapienza", Italy), Maurizio Falcone (Universita' di Roma "La Sapienza", Italy) IC/MT3369/025

We present a strategy for constructing large time-step (or semi-Lagrangian) schemes for geometric equations arising in front propagation models, like advection-driven, eikonal and curvature-driven propagation. The scheme stems from a suitable representation formula for the solution and allows for large time steps without stability losses. While the basic scheme is obtained for the codimension-1, evolutive Mean Curvature Motion, we also present a time-adaptive, a stationary and a codimension-2 version. Numerical tests on classical front evolution benchmarks will also be shown.

Evolutions by crystalline mean curvature. **Antonin Chambolle** (École Polytechnique, France) IC/MT1558/025

I will discuss some recent results, obtained in collaboration with G. Bellettini, V. Caselles, M. Novaga, on the crystalline mean curvature flow of surfaces. These include existence and uniqueness of convex flows, existence of convex flows with forcing term, including with constant volume, convergence to regular flows of (crystalline) "diffusion-generated" motions, implicit discretization by a variational approach (following Almgren-Taylor-Wang's or Luckhaus-Sturzenhecker's ideas) and numerical implementation by combinatorial optimization techniques (in collaboration with J. Darbon).

IC/MP107/025: Recent advances in front propagation modelling and applications. #2

Co-organiser: Regis Monneau (Ecole Nationale des Ponts et Chaussées, France)

(For abstract, see session #1 above.)

Very-weak solutions for a dislocation dynamics model. **Pierre Cardaliaguet** (Université Brest, France) IC/MT1458/025

In some models of dislocation dynamics one is lead to solve an Eikonal equation involving a (non-monotone) non-local term. Existence of classical viscosity solutions for such an equation is not known in general. In this joint work with G. Barles, O. Ley and R. Monneau we investigate a notion of very weak solution for such a model. We prove the existence of these solutions and show that they coincide with the classical viscosity solutions in cases where these latter are known to exist.

A generalized fast marching method applied to dislocations dynamics. **Elisabetta Carlini** (Università degli Studi di Roma "La Sapienza", Italy), Maurizio Falcone (Universita' di Roma "La Sapienza", Italy), Regis Monneau (Ecole Nationale des Ponts et Chaussées, France) IC/MT3373/025

We study dislocation dynamics with a level set point of view. The model represents a dislocation in a 2D plane by the zero level set of the solution of a non local and non convex eikonal equation. We first present a new Fast Marching algorithm for a non-convex eikonal equation modeling front evolutions in the normal direction. The algorithm is a generalization of the Fast Marching Method since the new scheme can deal with a *time-dependent* velocity without *any restriction on its sign*. We prove its convergence in the class of discontinuous viscosity solutions. We then extend the algorithm to evolutions with non local speed and we present some numerical simulations of fronts propagating in $\mathbb{R}^2$ applied to dislocations dynamics. Joint work with: M. Falcone, N. Forcadel, R. Monneau.

Recent advances in the level-set method for shape and topology optimization. **Francois Jouve** (Université Paris VII, France), Grégoire Allaire (École Polytechnique Palaiseau, France) IC/MT3783/025

Since the seminal papers in the early 2000s, there has been a burst of publications on the application of the level set method to shape and topology optimization of structures. Most of the recent papers focus on numerical issues for improving the level set method but do not extend so much its range of applicability. Let us mention, for example, works on its coupling with the topological gradient for holes nucleation or velocity/derivative regularization. Most of these recent works consider only compliance optimization which is a notably simpler problem than optimization of a general objective function.

We propose to extend the range of objective functions which are successfully treated by the level set method, and more specifically to treat the case of objective functions depending on the stress tensor. Together with our previous works (eigenvalue and multiple loads optimization, nonlinear elasticity problems, robust or worst-case optimization) it clearly demonstrates that the level set method is a versatile tool for structural optimization which can tackle industrial, and not merely academic, problems.

Front propagation in inverse problems and imaging. **Martin Burger** (Universität Münster, Germany) IC/MT1154/025

In this talk we shall discuss some (mainly nonlocal) front propagation problems arising in the solution of shape reconstruction and segmentation problems. It has become a popular solution method in the last years to construct solution schemes by propagation fronts along negative shape gradients of associated objective functionals. We shall discuss some practical and theoretical issues related to this approach.

In addition we shall comment on the need of additional nucleation mechanisms, e,g. forced by topological derivatives, in order to reach global minima of the objective functionals.

IC/MP117/002: Applications and numerical approximations of geometric partial differential equations.

Organiser: Xiaobing Feng (University of Tennessee, USA)
Co-organiser: Andreas Prohl (Eberhard Karls Universität Tübingen, Germany)

The aim of this minisymposium is to bring together some of world leading active researchers in the area of numerical geometric partial differential equations to present, communicate, and discuss recent developments and advances in numerical methods and simulations of geometric PDEs. Emphases will be given on the algorithmic development, numerical analysis, and emerging applications.
Topics to be covered in the minisymposium are:

1. Development and analysis of efficient discretization methods for geometric PDEs;
2. Development and analysis of fast converging adaptive solution algorithms;
3. Simulations of formations of singularities and continuation past singularities.
4. Applications of geometric PDEs in physics, biology, materials and image science.

Some adaptive methods in geometric analysis and physics. **Michael Holst** (University of California, San Diego, USA) IC/MT3428/025

There is currently tremendous interest in geometric flows due in part to the Ricci flow program in geometric analysis and in part to the recent construction of gravitational wave detectors around the world. In this lecture, we consider some nonlinear stationary and evolution systems arising in Einstein flow. We develop some basic estimates for one of these systems, and then derive *a priori* and *a posteriori* error estimates for Petrov–Galerkin methods. We develop some nonlinear approximation algorithms based on error indicator-driven adaptive methods, and outline some results on convergence and complexity. We illustrate some of the techniques with examples using the Finite Element ToolKit (FETK).

Retrieving topological information from the phase-field description of geometric evolution. **Qiang Du** (Pennsylvania State University, USA) IC/MT3671/025

Phase field and diffuse interface are popular methods for the modeling and simulations of evolving interfaces. They do not track the interface explicitly, and are insensitive to topological events. In some areas of applications, detecting and controlling topological change may be important. In this talk, we discuss some recent works with colleagues at Penn State on the development of effective formula for retrieving topological information within the phase field framework.

Gradient flows for shape optimization and applications. **Ricardo Nochetto** (University of Maryland, USA) IC/MT3726/025

We present a variational framework for shape optimization problems that hinges on devising energy decreasing flows based on shape differential calculus followed by suitable space and time discretizations (discrete gradient flows). A key ingredient is the flexibility in choosing appropriate descent directions by varying the scalar products, used for computation of normal velocity, on the deformable domain boundary. We discuss applications to image segmentation, optimal shape design for PDE, and surface diffusion, along with several simulations exhibiting large deformations as well as pinching and topological changes in finite time. This work is joint with E. Baensch, G. Dogan, P. Morin, and M. Verani.

A level-set approach to anisotropic flows with curvature regularization. **Frank Haußer** (FZ caesar, Germany), Axel Voigt (FZ caesar, Germany), Martin Burger (Universität Münster, Germany), Christina Stöcker (FZ caesar, Germany) IC/MT3604/025

Modeling and simulation of faceting effects on surfaces are topics of growing importance in modern nanotechnology. Such effects pose various theoretical and computational challenges, since they are caused by non-convex surface energies, which lead to ill-posed evolution equations for the surfaces. In order to overcome the ill-posedness, regularization of the energy by a curvature-dependent term has become a standard approach, which seems to be related to the actual physics, too. The use of curvature-dependent energies yields higher order partial differential equations for surface variables, whose numerical solution is a very challenging task.

In this paper we investigate the numerical simulation of anisotropic growth with curvature-dependent energy by level set methods, which yield flexible and robust surface representations. We consider the two dominating growth modes, namely attachment-detachment kinetics and surface diffusion. The level set formulations are given in terms of metric gradient flows, which are discretized by finite element methods in space and in a semi-implicit way as local variational problems in time. Finally, the constructed level set methods are applied to the simulation of faceting of embedded surfaces and thin films.

IC/MP117/002: Applications and numerical approximations of geometric partial differential equations. #2

Organiser: Xiaobing Feng (University of Tennessee, USA)
Co-organiser: Andreas Prohl (Eberhard Karls Universität Tübingen, Germany)

(For abstract, see session #1 above.)

Convergence of discrete schemes for the Perona–Malik equation. **Giovanni Bellettini** (Dipartimento di Matematica, Universita' di Roma To, Italy) IC/MT2712/025

We discuss the convergence of the spatial semi-discrete scheme for the one-dimensional Perona–Malik equation $u_t = (\phi'(u_x))_x$, $\phi(p) := \frac{1}{2}\log(1+p^2)$, when the initial datum $\overline{u}$ is 1-Lipschitz out of a finite number of jump points, and also in the more difficult case when $\overline{u}$ has a whole interval where $\phi''(\overline{u}_x)$ is negative. In the latter case, the limit solution u we obtain is the same as the one obtained by replacing $\phi(\cdot)$ with the truncated function $\min(\phi(\cdot),1)$, and it turns out that u solves a free boundary problem. Finally, we consider the limits of the full space-time discretization (implicit in time) of the Perona-Malik equation. Work in collaboration with M. Novaga (Dipartimento di Matematica, Università di Pisa, Largo B. Pontecorvo 5, 56127 Pisa, Italy, E-mail: novaga@dm.unipi.it), M. Paolini (Dipartimento di Matematica e Fisica, Università Cattolica di Brescia, via Trieste 41, 25121 Brescia, Italy, E-mail: paolini@dmf.unicatt.it) and C. Tornese (Dipartimento di Matematica, Università di Roma "Tor Vergata", via della Ricerca Scientifica, 00133 Roma, Italy, E-mail: tornese@mat.uniroma2.it).

Combination of global and local approximation schemes for harmonic maps. **Sören Bartels** (Humboldt-Universität zu Berlin, Germany) IC/MT3308/025

It is well understood that a good way to discretize a pointwise length constraint in partial differential equations or variational problems is to impose it at the nodes of a triangulation that defines a lowest order finite element space. In this talk we pursue this approach and discuss the iterative solution of the resulting discrete nonlinear system of equations for the simplest model problem that defines harmonic maps into spheres. An iterative scheme that is globally convergent and energy decreasing but slowly convergent is combined with a locally, rapidly convergent approximation scheme. An explicit example proves that the local approach alone may lead to ill-posed problems; numerical experiments show that it may actually diverge or lead to highly irregular solutions with large energy if the starting value is not chosen carefully. A combination of the global and local method defines a reliable algorithm that performs very efficiently in practice and provides numerical approximations with bounded energy.

A finite-element method for Landau–Lifschitz equations. **François Alouges** (Université Paris-Sud, France) IC/MT3738/025

The behavior of the magnetization inside a ferromagnetic body is modelized by the Landau–Lifchitz equations. These equations write down as a non-linear, slightly dissipative, partial differential equation whose unknown is the magnetization, a 3 dimensional vectorfield which is assumed to be of constant magnitude throughout the body. When one wants to solve numerically these equations, one usually faces the problem of taking into account the (non-convex) constraint that the magnetization belongs to the unit sphere $\mathbb{S}^2$ of $\mathbb{R}^3$ at every point. Besides that, it is of high importance for real applications that the scheme does not produce too much artificial viscosity and is also consistent with the original problem. Writing finite element schemes in that framework - though not obvious - is also challenging because the shapes of the objects that physiscists consider may be (and actually are) arbitrary.

In this talk, we will present some of the latest results, both analytical and numerical, in that direction focusing on the interaction between the nonlinearity due to the constraint and the terms in the equation which come from the model.

Recent developments on numerical methods for second-order fully-nonlinear PDEs. **Xiaobing Feng** (University of Tennessee, USA) IC/MT1977/025

In this talk, I shall discuss some recent developments on numerical approximations of 2rd order fully nonlinear PDEs. The focus of the talk will be on presenting a newly developed vanishing moment method and the notion of moment solutions for 2rd order fully nonlinear PDEs and on discussing the convergence of the method and the relationship between moment solutions and viscosity solutions. The vanishing moment method combined with existing wealthy numerical methods/algorithms for high order quasilinear PDEs makes it possible to construct practical and convergent numerical methods for computing moment and viscosity solutions of 2rd order fully nonlinear PDEs, a task which was largely untouchable before. I shall also present some numerical experiment results for the Monge-Ampere equation, the Gauss curvature equation, and the infinite Laplace equation to demonstrate both convergence and efficiency of the vanishing moment methodology for solving 2rd order fully nonlinear PDEs.

This is a joint work with Michael Neilan of the University of Tennessee, U.S.A.

IC/MP37/025: Modeling and numerical methods for multi-dimensional and multi-physical problems.

Organiser: Juergen Geiser (Humboldt-Universität zu Berlin, Germany)

The motivation for this mini-symposium came from the need to solve complex physical based models. The amount of new methods has increased in the last years but a simplification should took place to solve the complicate models. Complicated models in material and environmental science are possible to solve with such discretisation and solver methods, that are parallel and adaptive. Because of the tremendous interest in climate change, material research and air pollution the development in this direction has increase enormously. These problems are recently actual and interest the people in the western civilization. For such problems a huge class of iterative solver methods are developed. We will focus on advanced discretization and iterative solver methods which are more effective and appropriate to the problems. In this case the class of implicit-explicit and splitting methods could reach a new quality to solve such complicate problems. In the past many software tools have been developed for one-dimensional and simple physical problems; e.g., one-dimensional transport codes or reaction-codes based on ODEs. But the future interests will be coupling of such simple physical and one-dimensional problems to multi-physical and multi-dimensional problems. In this field the coupling of various software tools are interested to simulate the forced complex models. The software recycling and re-engineering of such coupled models will reduce the programming time and lead complex models to adequate applications.

We would like to bring numerical analysts, software developer, modelers, applied engineers and physicists together to discuss methods based on discretization and iterative solver methods for models in solid and fluid mechanics.

Adaptive split schemes for quenching problems. **Qin Sheng** (Baylor University, USA) IC/MT3524/043

This talk concerns certain adaptive finite difference methods for solving multidimensional quenching differential equations,

$$u_t = a^2(u_{xx} + u_{yy}) + \frac{c}{(1-u)^2}.$$

Splitting strategies will be used to achieve the efficiency as well as accuracy of the numerical methods. Analysis on the stability, monotonicity and global error estimates will be given.

Numerical examples will be given to illustrate our results.

Splitting methods for molecule orientations of liquid crystals and liquid-crystal flows. **Ping Lin** (National University of Singapore) IC/MT3279/025

The liquid crystal molecule orientation is arranged by minimizing so-called Oseen–Frank energy functional. The energy is nonconvex due to the unit-length constraint of liquid crystal molecules and the constraint is treated by the penalty method. A time-splitting method is used to compute the solution and its orientation singularities. The liquid crystal flow is a coupling between a director field (molecule orientation) of liquid crystals and a flow field. The model is also related to phase field models of multiphase flows and to microfluidics device. It is crucial to preserve the energy law of the system in numerical simulation, especially when orientation singularities are involved. We present a discrete energy law preserving C0 finite element method. A fixed point iterative method is presented to split the director and flow fields and to achieve a matrix free method in time. A number of liquid crystal and liquid crystal flow examples are computed to demonstrate our algorithms.

Robust error control of Cahn–Hilliard equations with elasticity. **Rüdiger Müller** (Humboldt-Universität zu Berlin, Germany) IC/MT4142/025

Phase separation of an initially homogeneous mixture into different phases can be modeled by the Cahn-Hilliard equation. The interface thickness between the bulk phases enters as a small parameter ϵ into this fourth order semilinear parabolic equation. We also consider the case that elastic stresses due to the lattice misfit become important and the equation has to be coupled to an elliptic system.

When ϵ is very small numerical methods could take great advantage of adaptive mesh refinement that requires error control based on a-posteriori estimators. The numerical analysis of the Cahn-Hilliard equation is well established for fixed parameter size ϵ. But up to now, a-posteriori error estimates depend exponentially on ϵ^{-1} and thus become useless for small ϵ.

In this talk we present an a-posteriori error estimate, that only depends on a low order polynomial of ϵ^{-1}. It is based on the observation that the lowest eigenvalue of the linearized problem is bounded, as long as no topological changes occur. On the other hand, by monitoring this eigenvalue, critical points in the solution can be detected. The results are illustrated with numerical experiments using finite elements and adaptive multigrids.

Description of light focusing by a spherical lens using diffraction integral method. **Shekhar Guha** (Air Force Research Lab., Wright–Patterson AFB, USA), Leonel Gonzalez (General Dynamics Corporation, USA) IC/MT3779/025

A full diffraction theory describing the focusing of light by an arbitrary lens element is not easily available. The complications arise from the inapplicability of the paraxial approximation and the Śthin-lensŠ approximation to the case of light focusing by a general ŚthickŠ lens having a small f-number. When these approximations are not used, the computation time involved in evaluating the diffraction integrals becomes very large for ordinary size lenses (1 cm or larger) for light wavelengths in the visible and infrared wavelengths (400 nm Ű 10000 nm). In this work, we will present the results of application of the Stratton-Chu vector diffraction integrals to a lens having two spherical surfaces, on one of which a plane wave of light is incident. The values of the fields on the second surface and then the field propagated outside the lens will be calculated by repeated use of the diffraction integrals. The limits of computation using current resources will be explored and experimental measurements verifying the calculated results will be presented.

IC/MP223/025: High-resolution discretizations of initial boundary-value problems.

Organiser: Thomas Hagstrom (The University of New Mexico, USA)
Co-organiser: Timothy Warburton (Rice University, USA)

To solve difficult problems in computational science and engineering high-resolution methods allowing a minimal number of degrees-of-freedom per wavelength are required. The difficulty is to effectively apply such methods in complex geometry or for nonlinear problems. The speakers in this minisymposium will discuss a variety of techniques for stably implementing efficient approximation schemes for challenging applications, with a focus on hyperbolic systems of partial differential equations. Examples include high-order discontinuous Galerkin methods on unstructured grids as well as high-order difference approximations on block-structured or purely Cartesian grids with embedded boundaries. Issues to be addressed include:

- The avoidance of excessive time-step stability constraints associated with one-sided approximations or small cells;
- Discrete stability estimates and stability;
- Robust treatment of singularities;
- Exploration of non-polynomial bases;
- Demonstration of serious applications and general-purpose software.

Taming the CFL condition of the discontinuous Galerkin method. **Timothy Warburton** (Rice University, USA) IC/MT3410/025

The upwind discontinuous Galerkin method is an attractive method for solving time-dependent hyperbolic conservation laws. It is possible to use high-order explicit time-stepping methods and high-order spatial approximations without incurring heavy numerical linear algebra overheads. However, the Courant-Friedrichs-Lewy (CFL) condition for these methods depends on the polynomial order used and there is a somewhat excessive cost for using very high order spatial approximation. We will discuss the impact of a staggered grid based filter on the CFL number for these methods and present an algorithm which has CFL number independent of the spatial order of approximation. We will also present computational results for advection, advection-diffusion, and the wave equation on one-dimensional meshes using up to tenth order in space and time.

Finally, we will compare the efficiency of the staggered grid filter with a second approach for taming the CFL condition based on the Koslov/Tal-Ezer mapping technique.

A stable high-order finite-difference scheme for the Navier–Stokes equations. **Jan Nordström** (FOI and Uppsala University, Sweden) IC/MT2206/025

We discuss various aspects of a high order finite difference scheme applied to the Navier-Stokes equations. We discuss the stability obtained by using the concept of summation-by-parts operators in combination with the weak penalty technique for imposing boundary and interface conditions. We adress different aspects of the weak boundary conditions such as accuracy, stability, errorbounds and the reflective/non-reflective properties.

We also show how to construct a stable and accurate hybrid method for nonlinear phenomenona in complex geometries in combination with requirements of accurate signal transportation in domains with smooth flow and geometries. Two separate solvers, one the high order finite difference method discussed above and another using the node-centered unstructured finite volume method is coupled in a truly stable way. The two flow solvers run independently and recieve and send information from each other by using a third coupling code.

The potential of the CELL *processor for improving the numerical efficiency of discontinuous Galerkin methods.* **Jean-François Remacle** (Universite Catholique de Louvain, Belgium) IC/MT3339/025

In this talk, we will present a strategy that enables to solve large scale CFD problems using the new CELL processor.

The new CELL processor combines the considerable floating point resources required for demanding numerical algorithms with a power- efficient software-controlled memory hierarchy. Despite its radical departure from previous mainstream/commodity processor designs, Cell is particularly compelling because it will be produced at such high volumes that it will be cost-competitive with commodity CPUs.

High order Discontinuous Galerkin methods are characterized

by high computational intensity and regular memory access patterns, making them an extremely well suited candidate for the Cell architecture. In a recent work, Williams et al. have used the CELL processor for doing BLAS3 DGEMM matrix-matrix computations. An outstanding performance of about 200 GFlops was observed. We have all the reasons to believe that the CELL and the DGM will be able to develop lots of affinities.

Yet, a main concern of ours is to maintain the memory signature of the method as low as possible while obtaining a quadratic convergence in the resolution of non linear systems. This has led us to develop a Newton-Krylov solver coupled with a p-multigrid preconditionner. The oveall implicit strategy will be given and first computations with the CELL will hopefully presented.

IC/MP223/025: High-resolution discretizations of initial boundary-value problems. #2

Organiser: Thomas Hagstrom (The University of New Mexico, USA)
Co-organiser: Timothy Warburton (Rice University, USA)

(For abstract, see session #1 above.)

Stabilizing high-resolution one-sided difference operators. **Thomas Hagstrom** (The University of New Mexico, USA) IC/MT2715/025

For the numerical simulation of waves, the benefits of high-resolution discretizations with small dispersion errors are clear. However, near physical or element boundaries the direct use of wide-stencil, one-sided formulas whose accuracy matches that of the interior scheme typically leads to instabilities associated with the Runge phenomenon. For polynomial-based pseudospectral methods these instabilities are partially suppressed through the use of an appropriately graded mesh with quadratic clustering near the boundaries. There is still a cost; namely the bounds on the derivative operator grow quadratically with the polynomial degree.

In this talk we focus on the issue of optimal subsampling near the boundary for high-resolution difference formulas. We show experimentally that high-order (up to 22) one-sided difference formulas can be stabilized by the addition of $1-3$ subcell nodes without the excessive growth of the norm of the operator inherent in Chebyshev clustering. We also consider the generalization of the construction to optimized discretizations such as Tam's DRP schemes as well as difference methods built from band-limited bases such as the Knab-Whittaker functions. We present results from experimental codes implementing this construction on overlapping composite grids both for first-order and second-order hyperbolic systems.

A defect of the analysis we have performed so far is that it is almost entirely experimental. We close with some ideas about developing a comprehensive theory of subsampling and extrapolation.

Fast solver for the heat equation in unbounded domains. **Jing Rebecca Li** (INRIA Rocquencourt, France), Leslie Greengard (Courant Institute, NYU, USA) IC/MT2689/025

We describe a fast solver for the inhomogeneous heat equation in unbounded domains. It relies on several new tools: the spectral approximation of the free-space heat kernel, the nonuniform fast Fourier transform, and accurate quadrature methods for the evaluation of heat potentials. Unlike finite difference and finite element techniques, diffusion into an infinite medium is satisfied analytically, avoiding the need for artificial boundary conditions on a finite computational domain. The method is explicit, unconditionally stable, and requires an amount of work of the order O(M N log N) where N is the number of discretization points in physical space and M is the number of time steps.

An example from dendritic solidification will be presented.

Plane-wave approximations for Maxwell's equations in isotropic and anisotropic media. **Tomi Huttunen** (Kuopion Yliopisto, Finland), Peter Monk (University of Delaware, USA) IC/MT2979/025

We investigate the Ultra Weak Variational Formulation (UWVF) of Maxwell's equations for approximating electromagnetic wave fields in isotropic and anisotropic media. We show that the UWVF method can be considered as a Discontinuous Galerkin method when the test functions are local solutions of the Maxwell system. Hence, as proposed by the originators of the UWVF, a linear combination of plane waves can be used for the elementwise approximation of the wave field. However, the number of basis functions for each element must be chosen carefully to avoid ill-conditioning of the resulting matrix equation. Parallelized 3D numerical simulations suggest that the UWVF can successfully simulate wave propagation in isotropic media at relatively high wave numbers. Furthermore, we show that it is possible to extend the method to problems in anisotropic media.

IC/MP276/025: Numerical methods for multicomponent flows.

Organiser: Alexander Kurganov (Tulane University, USA)
Co-organiser: Alina Chertock (North Carolina State University, USA)

Multicomponent flow models arise in many different applications including mixing processes, bubbly flows, liquid suspensions, multilayer shallow water equations, and many others. These models can be divided into two major groups. The first one consists of models where the fluids interface can be practically tracked: a multifluid technique is then applied near the interface only, while away from it a single fluid method(s) can be safely used. When the number of material interfaces increases beyond the practically traceable one, the second group of models is typically used. The equations now describe the fluids mixture, in which all fluid components are assumed to be present and the conservation laws are written for the volume/mass fractions of each phase. No interface tracking is then needed, but the main difficulties are loss of hyperbolicity and/or presence of nonconservative terms that make both analysis and numerical treatment of multiphase models extremely challenging. In the limiting cases, the models from both groups may serve as two possible alternatives to describe the same physical phenomenon.

Development of highly accurate and reliable numerical methods for multicomponent models is of great importance for understanding the aforementioned physical systems. Multifluid numerical algorithms based on a direct extension of single fluid approaches may run into unexpected difficulties due to nonphysical oscillations generated across material interfaces, lack of hyperbolicity and/or a naive discretization of nonconservative terms. Thus, derivation of new genuinely multicom-

ponent techniques is absolutely necessary in the presence of fluid interfaces and interactions between the flow components. In this mini-symposium, speakers will describe their latest progress in development of new numerical methods and improvement of existing ones for both types of the above described models.

Solving the derivative Riemann problem for the Baer–Nunziato equations. **Eleuterio Toro** (Università degli Studi di Torino, Italy) IC/MT3765/025

In this paper we construct semi-analytical solutions to the derivative Riemann problem (DRP) for the Baer–Nunziato (BN) equations for compressible two phase flows. The DRP is the Cauchy problem for the relevant system of equations in which the initial condition consists of two smooth vectors separated by a discontinuity at the origin. The solution, as a function of time, is sought right at the interface. The technique used [1], [2] is an extension of the Cauchy-Kowaleski method and expresses the solution as a power series expansion at the origin. The determination of the leading term requires the solution of a classical Riemann problem for the full BN system. Exact and approximate solvers are discussed for this purpose. The high-order terms require the solution of a sequence of linearized homogeneous Riemann problems for spatial derivatives.

The solutions are systematically assessed against reliable reference solutions obtained numerically. Application of the solutions to construct numerical schemes for solving numerically the general initial-boundary value problem following the ADER approach [3]-[4] for the BN system are also discussed.

Work done in collaboration with Cristobal E Castro.

Hybrid schemes for flows in porous media. **Smadar Karni** (University of Michigan, Ann Arbor, USA) IC/MT2737/025

The Baer–Nunziato two-phase flow model describes flow over a porous bed. It forms a hyperbolic system which is nonconservative due to porosity changes. If the porosity is contant in each phase, the model reduces to two conservative subsystems separated by an interface across which the porosity changes. Numerical solutions may produce completely non-physical solutions, a failure that is attributed to their inability to preserve the entropy across porosity jumps. We present numerical methods that do not produce entropy across porosity jumps, and illustrate their suitability for computations of two-phase flow in porous media for stationary and moving porosity interfaces.

Interface coupling of different models for multiphase flows. **Nicolas Seguin** (Université Pierre et Marie Curie, France) IC/MT1309/025

We present the coupling of different models for multiphase flows. Several models can be coupled, such that two-velocity systems, drift-flux models and homogeneous models. The coupling of general hyperbolic systems will be presented and several examples of coupling will be studied, including the interaction of pressure waves with the interface of coupling.

Thin-film flow influenced by thermal fluctuations. **Günther Grün** (Universität Erlangen–Nürnberg, Germany) IC/MT4702/025

We will be concerned with the effects thermal fluctuations have on spreading and dewetting of thin liquid films. Starting from the incompressible Navier-Stokes equations with noise, a stochastic fourth-order degenerate parabolic equation for the evolution of the film height can be derived – the stochastic thin-film equation. Besides the usual deterministic terms, it contains multiplicative noise within a convective term. We propose a discretisation scheme and we present integral estimates suggesting the existence of a.s. non-negative solutions. Finally, we give both formal and numerical evidence for our conjecture that thermal fluctuations may resolve discrepancies w.r.t. timescales of dewetting between physical experiments and deterministic numerical simulations. This is joint work with N.Dirr, K.Mecke, M.Rauscher.

IC/MP276/025: Numerical methods for multicomponent flows. #2

Central-upwind schemes for compressible multi-component fluids. **Alexander Kurganov** (Tulane University, USA) IC/MT3234/025

We focus on development Godunov-type central schemes for hyperbolic systems of conservation and balance laws and on their applications to several multi-component models.

Central schemes are simple, robust, and universal methods for general multi-dimensional systems and they can be applied as a black-box solver to a wide variety of problems arising in many different fields. The simplest central scheme is the celebrated Lax-Friedrichs scheme. It is truly robust, but it suffers from an excessive numerical dissipation. Since the end of 1980, several high-resolution central schemes have been proposed following the pioneering work by Nessyahu and Tadmor. We have been working on development of a subclass of central schemes, the so-called central-upwind schemes, which further reduce numerical dissipation present in central schemes by incorporating some upwinding information. At the same time, central-upwind schemes enjoy the major advantage of central schemes: the use of (approximate) Riemann problem solver is avoided.

Applying central-upwind schemes to multi-component flows requires development and implementation of several numerical techniques specifically designed to track the interface between non-mixing fluids; to extract information from the "mixed" computational cells, where the fluids numerically mix (or to replace the information there with a reliable interpolation); to deal with nonconservative exchange terms, which may cause severe numerical oscillations; and several others. These numerical techniques are crucial for successful application of both central and other finite-volume schemes, and we will discuss them in details.

Interface-tracking method for compressible multifluids. **Alina Chertock** (North Carolina State University, USA), Smadar Karni (University of Michigan, Ann Arbor, USA), Alexander Kurganov (Tulane University, USA) IC/MT2738/025

I will present a new finite-volume method for compressible multi-fluid models, in which the fluids are assumed to be separated by the interface[1]. Away from the interface both fluids are described by the Euler equations of gas dynamics with different equations of state (stiff equations of state allow us to model liquid components of multi-fluids). Switching between the equations of state across interfaces makes designing of stable and highly accurate numerical method quite challenging, since appearance of artificially *mixed* cells may lead to significant pressure oscillations (see, e.g.,[2] and the references therein).

The main idea in designing the proposed method is to allow appearance of the *mixed* cells while avoiding the use of the information from these cells in the evolution of the numerical solution. The method is based on tracking the interface (with the help of the level set, particle method, or any other technique) and using special upwinding procedure for computing the numerical fluxes between the mixed cells and their neighbors. Away form the interfaces, any *regular* numerical flux can be used (we have utilized the second-order central-upwind numerical fluxes). When the interface remains in the same cell after one time step, the evolved solution is oscillation-free. However, when the interface propagates to the neighboring cell, we use another upwinding procedure to replace the value in the *corrupted* cell, while the values of the solution in a new mixed cell are computed from the total mass, momenta and energy conservation requirements.

I will show several one- and two-dimensional examples demonstrating the superior performance of the method: very high resolution of contact/material interfaces and lack of oscillations across them.

Central-upwind schemes for two-layer shallow-water equations. **Guergana Petrova** (Texas A&M University, USA), Alexander Kurganov (Tulane University, USA) IC/MT1619/025

We derive a second-order semi-discrete central-upwind scheme for the system of two-layer shallow water equations. We prove that the presented scheme is well-balanced and positivity preserving, that is, the depth of each fluid layer is guaranteed to be nonnegative. We also propose a technique for the treatment of the nonconservative interlayer exchange terms.

Our numerical experiments clearly indicate the sharp resolution of the computed solution, the ability to preserve steady states, and the robustness of the proposed method.

A relaxation–projection method for compressible single phase and multiphase flows. **Richard Saurel** (Université de Provence Aix-Marseille I, France) IC/MT1712/025

The numerical diffusion of interfaces separating compressible fluids involves artificial mixtures for which the determination of the correct thermodynamical state is difficult. By considering such zones as physical multiphase mixtures appropriate hyperbolic models can be derived (Saurel, 2007). These models are non conservative, but shock relations are available (Saurel et al., 2006a). Consequently, exact and approximate Riemann solvers can be derived.

However, the numerical approximation of these models poses extra difficulties. The main one is related to the cell average of non-conservative variables. The Godunov average is shown to result in important inaccuracies. To circumvent this difficulty a new relaxation scheme is built (Saurel et al., 2006b). The cell pressure and volumes fractions are determined by solving a relaxation system involving the various sub-volumes and states present in a cell. These sub-volumes correspond to the distances travelled by the various waves emerging of cell boundaries to the interior of the cell. The interactions between the various non-equilibrium sub-volumes are used to build a relaxation system. Its asymptotic solution provides the cell thermodynamic state. This method is very efficient for interface problems even with very large density and pressure ratios.

Strong shock propagation in multiphase mixtures poses another computational challenge related to the partition of the energy among the various phases. Knowledge of the shock relations and Riemann problem solution is not sufficient with non-conservative systems to guaranty convergence of the solution. Examples and possible solutions will be presented.

IC/MP4420/025: Recent advances in interface methods and applications in multi-phase problems.

Organiser: Zhilin Li (North Carolina State University, USA)
Co-organiser: Xiaolin Li (SUNY at Stony Brook, USA)
Co-organiser: Kazufumi Ito (North Carolina State University, USA)

In this min-symposium, the speakers will present their recent research on numerical methods and application to multi-phase flows. Many scientific and engineering problems require a detailed understanding of physics coupled across a dynamically moving interface separating multi-material or multiphase domains. This minisymposium focus on numerical methods in dealing with such problems. The presentations in this minisymposium will address the propagation of the interface geometry, the coupling across the interface of the interior physics on each side of the interface and the physics at the boundary defined by the moving interface.

A grid-based tracking method for moving interface problems. **Hongkai Zhao** (University of California, Irvine, USA) IC/MT1627/026

I will present a new numerical formulation that combines Eulerian and Lagrangian methods naturally for moving interface problem.

A high-order ENO conservative Lagrangian scheme. **Juan Cheng** (IAPCM, Beijing, PR China) IC/MT1499/026

We present a newly developed Lagrangian scheme for solving Euler equations which is based on high order essentially non-oscillatory (ENO) reconstruction. The scheme is conservative for density, momentum and total energy, maintains formal high order accuracy and can achieve at least second order accuracy with moving and distorted Lagrangian meshes, is essentially non-oscillatory, and has no parameters to be tuned for individual test cases. Comparing with many current Lagrangian schemes, our ENO scheme overcomes some of their disadvantages such as non-conservativity of momentum and total energy, low accuracy, and the existence of parameters which must be adjusted for individual test cases. One and two dimensional numerical results will be given to demonstrate the performance of the scheme in terms of accuracy, resolution for discontinuities, and non-oscillatory properties.

Keywords: Lagrangian scheme; high order accuracy; conservative; ENO reconstruction; Euler equations

Green's function approach for elliptic problems with interfacial discontinuity. **Do Wan Kim** (Hanyang University, Republic of Korea), Sukky Jun (University of Wyoming, USA), Seong-Kwan Park (Yonsei University, Republic of Korea) IC/MT2610/026

Although the elegance of the Green's function has attracted many researchers into the integral equation method for decades, higher dimensional Green's function still remains intricate due to the difficulty in managing the singularity and complex geometry. For example, the Green's functions in 2D and 3D for the Poisson problem have logarithmic and pole singularities, respectively. Furthermore, the Green's function has to satisfy homogeneous boundary condition in the Dirichlet problem, which often becomes a strong restriction on the availability for complex geometries.

In this talk, we present a novel Green's function method to effectively solve the elliptic problems:

$$\nabla \cdot (\kappa \nabla u) = f \quad \text{in } \Omega, u|_{\partial\Omega} = u_B \text{ on } \partial\Omega,$$

which is subjected to the interface conditions

$$\left[\kappa \frac{\partial u}{\partial n}\right]_\Gamma = q_\Gamma, \quad [u] = h_\Gamma,$$

where an inclusion belongs to Ω, the boundary of the inclusion is the interface denoted by Γ, f and κ are bounded functions in space, and both q_Γ and h_Γ represents strengths of the single and double layer sources, respectively.

The key idea of the method is to use 1D Green's function only, even for the above multidimensional problems. It is sufficiently simple to obtain the 1D Green's function for various types of differential operators, and the singularity of the 1D Green's function is so weak enough to be handled. It can thus be applied to problems with complicated geometry such as interfacial discontinuity. In particular, the proposed method is not a differential but an integral scheme, so the stability can be assured. The mathematical error analyses will also be presented for both 1D and 2D elliptic problems.

Accurate numerical interface treatments for multiscale problems. **Thomas Hagstrom** (The University of New Mexico, USA) IC/MT2724/026

In recent years there has been great interest in multiscale computations, which we will take to mean the coupling of very fine scale models in small regions to coarser models in the bulk of the domain. Of fundamental importance for the success of this approach is the accurate exchange of information between the two domains. A number of distinct techniques for dealing with this issue have been proposed and implemented. They range from the derivation and direct implementation of nonlocal conditions, to semilocal approximations based on least squares fitting, to the use of ad hoc damping layers. Our goal in this talk is to review and analyze existing methods in the context of a unified mathematical framework. We will explore the analogies between the multiscale interface problem and the easier problem of radiation boundary conditions for hyperbolic systems. For the latter, an extensive theory exists and a number of very accurate and efficient methods are available. Lastly, we will present some numerical experiments to compare methods and assess the utility of the mathematical theory.

Adaptive algorithms for phase field models of some interface problems. **Qiang Du** (Pennsylvania State University, USA) IC/MT156/010

We present our on-going works with colleagues at Penn State on the numerical algorithms for the phase field simulations of some interface problems, ranging from microstructure evolution in multicomponent alloy to multicomponent lipid vesicles. We discuss recent development of highly adaptive computational algorithms for large scale phase field simulations. We also address how to effectively retrieve useful statistical information within the phase field framework.

Validation of turbulent-mixing simulations. **James Glimm** (SUNY at Stony Brook, USA) IC/MT415/010

We consider the mixing zone generated by steady acceleration of a fluid interface between two fluids of different densities (Rayleigh-Taylor instability). Recent improvements to the front-tracking algorithm FronTier and to the modeling of transport phenomena in these simulations allows agrement between simulation and experiment for a number of experimental cases. Closures for averaged equation mixing models show good agreement when compared to such direct simulations.

An interoperable front-tracking code and applications to various scientific problems. **Xiaolin Li** (SUNY at Stony Brook, USA), James Glimm (SUNY at Stony Brook, USA) IC/MT1491/026

We introduce an enhanced front tracking method and its software implementation with an easy-to-use user interface. New algorithms include conservative coupling in ND and locally grid based topological bifurcation for 3D. Objective mathematical and computational assessment are given with comparison to other interface methods such as the level set method and volume of fluid method. We emphasize the interoperability of front tracking with other scientific software including the combined operation with AMR and combustion packages. Scientific applications include the study of turbulent mixing due to acceleration driven instabilities, fuel injection jet, shock flame interaction, extending to cell motion in biology. This work is in collaboration with the FronTier Group at Stony Brook University.

Extension of the finite-difference Stokes solvers to irregular domain and two-phase problems. **Vita Rutka** (Universität Konstanz, Germany) IC/MT2576/026

The idea of Immersed Interface Methods (IIM) is to work on grids that do not have to be aligned to possible discontinuities in equation parameters and solution.

The Explicit Jump Immersed Interface Method (EJIIM) [Wiegmann, 1998], is a modification of the original IIM for elliptic partial equations, where the jumps in the unknown function and its Cartesian derivatives are introduced as explicit additional variables into the system. Near discontinuities, the standard numerical method, serving as the basis, is modified by adding correction terms that involve jumps in the function and its derivatives.

In the implementation of the method, the base numerical method, like central finite differences on a regular parallelepiped, can be clearly separated from the EJIIM correction due to the non-grid aligned boundary and/or interface.

We will analyse and compare different finite difference realizations of the Stokes equations coupled with the EJIIM. Issues like staggered versus non-staggered grid or saddle point formulation versus several Poisson problems will be discussed and compared in their performance.

A numerical method for soluble surfactants on moving interfaces. **Shilpa Khatri** (NYU/KTH, USA) IC/MT5058/026

In many real world multiphase flow problems, there are surfactants present. These are surface reacting agents that modify the strength of the surface tension. The concentration of the surfactant on the interface separating the fluids can be modeled with a time-dependent differential equation defined on the time-dependent and deforming interface. For soluble surfactants, this is also coupled to a PDE for the concentration of surfactants in the bulk.

We present a second order method based on an explicit but yet Eulerian discretization of the interface. We use standard finite difference schemes on the discretization of the interface to solve the PDE for the surface concentration. The PDE for the concentration in the bulk will, in the spirit of interface tracking methods, be solved on a fixed uniform grid. The interface arbitrarily cuts through the uniform grid so the boundary flux condition for the bulk surfactant needs a special treatment. We will discuss the details of this implementation and show results in two dimensions.

IC/MP177/025: Solution of the master equation in biochemistry.

Organiser: Per Lötstedt (Uppsala University, Sweden)
Co-organiser: Markus Hegland (Australian National University)

Simulation *in silico* of biological cells is important in the emerging field of systems biology. The macroscopic model equations for simulation of biochemical reactions in the cells are the reaction rate equations. They form a system of deterministic, nonlinear ordinary differential equations for the concentrations of the participating chemical species. This model is accurate for reactions with many participating molecules of each species. If the number of molecules is small or if the reactions occur far from thermodynamic equilibrium, then a stochastic model on a mesoscale such as the chemical master equation is a much more precise description. This is often the case in molecular biology where the majority of the reacting molecules are found in copy numbers less than one hundred in cells such as *Escherichia coli*.

The chemical master equation is a differential–difference equation for the time-dependent probability density of the number of molecules of each participating species. The spatial dimension of the problem is given by the number of species. Since this number may be many thousands in a cell and 10–100 in simpler models, the computational problem using standard methods is enormous with an exponential growth in work and storage with the number of species.

There are different ways of avoiding the *curse of dimensionality*. Sparse grids is a technique for sparse representation of smooth solutions in high dimensions. Gillespie's algorithm is a Monte Carlo method for generating trajectories of the chemical systems and it has been modified to include spatial diffusion. A hybrid method combines the macro and mesoscales and a deterministic algorithm with a Monte Carlo algorithm. These new methods will be described in the minisymposium and applied to many examples from molecular biology including gene regulatory networks.

Multi-scale modelling of biochemical systems by the chemical master equation. **Kevin Burrage** (University of Queensland, Australia) IC/MT1795/025

Biochemical reactions underlying genetic regulation are often modelled as a continuous-time, discrete-state, Markov process, and the evolution of the associated probability density is described by the so-called chemical master equation (CME). However the CME is typically difficult to solve, since the state-space involved can be very large or even countably infinite. Until now this has meant that the direct computation of the probability density function (pdf) associated with chemical kinetics that takes into account intrinsic noise has not been computationally feasible.

Recently a finite state projection method (FSP) that truncates the state-space has been suggested by Munsky and Khammash and shown to be effective on small scale problems. Presented in this talk is a Krylov FSP algorithm based on a combination of state-space truncation and inexact matrix-vector product routines. This allows larger-scale models to be studied and solutions for larger final times to be computed in a realistic execution time.

We compare the efficiency of this technique with trajectorial approaches such as the Stochastic Simulation Algorithm and also show how a strong trajectory can be computed directly from the pdf computed by the CME. Numerical results indicate that this new approach can be fast and is extendable to large biological models.

This is joint work with MARKUS HEGLAND, SHEV MACNAMARA, AND ROGER B. SIDJE

A master equation approach to stochastic reaction diffusion modeling of living cells . **Johan Elf** (Harvard University, USA) IC/MT1450/025

I will discuss how the reaction diffusion master equation [1] can be used to model stochastic reaction diffusion kinetics in intracellular chemical reaction pathways. The exceptionally high dimensionality of the equation makes it practically impossible to solve directly, instead I will describe an efficient Monte Carlo algorithm, the Next Subvolume Method [2], that generates statistically correct trajectories of the stochastic kinetics. Efficient implementation of the algorithm is finicky, why we have developed the MesoRD software [3]. MesoRD can be used to simulate general biochemical reaction networks described in SBML [4] in geometries described by CSG [5]. I will show how we have used MesoRD to understand noise induced ef-

fects in the spatiotemporal fluctuations of the Min proteins in the bacterium *E. coli* [6].

On the numerical solution of the master equations with sparse grids . **Markus Hegland** (Australian National University) IC/MT186/025

The understanding of complex biological pathways faces the challenge of many randomly interacting components. The evolving probablity distributions describing populations of such systems are modelled by the Chapman/Kolmogorov or chemical master equations. These probability distributions are used to describe the location and range of clusters of the population. They are also used for maximum likelihood methods for the determination of model parameters describing the propensities. However, the representation of these models does have to address the curse of dimensionality. In this talk we will discuss ways how this curse can be dealt with using sparse grid approximation techniques, and, in general, discuss numerical approximations used to solve the chemical master equations.

Hybrid method for the chemical master equation. **Per Lötstedt** (Uppsala University, Sweden) IC/MT1700/025

In the macroscopic model for chemical reactions, the reaction-rate equations are solved for the concentrations of the reacting chemical species. This is a good model if many molecules of each species are present. If there are few molecules of each kind as it often is in a biological cell, then a mesoscopic model including intrinsic noise is much more accurate. The standard method for solution of the mesoscopic master equation is Gillespie's Monte Carlo method. A hybrid method has been constructed combining the best features of both approaches. A stochastic model is introduced only where it makes a difference and the faster solution methods available for the deterministic reaction rate equations are used as much as possible. The reaction rate equations approximate the expected values of the concentrations obtained with the master equation. The expected values of the stochastic variables for the deterministic equations are computed by a quasi-Monte Carlo method. Examples from biochemical systems in molecular biology illustrate the method. This is joint work with Andreas Hellander.

IC/MP310/025: Computational advances in evolving interfaces.

Organiser: Karol Mikula (Slovak University of Technology Bratislava, Slovakia)
Co-organiser: James Sethian (University of California, Berkeley, USA)
Co-organiser: Peter Frolkovič (Universität Heidelberg, Germany)

Dynamic interfaces and moving free boundaries arise in a broad range of applications as material science, structural mechanics, computational fluid dynamics, image processing, computer vision and many others. They represent, e.g., the boundaries between solid and liquid phase in the solidification of materials, boundaries between immiscible liquids in multiphase flows, discontinuities representing edges in digital image segmentation, etc. An interface is represented by a closed curve in 2D or a hypersurface in 3D, and can be advected by an external velocity field and, moreover, its shape can be influenced by a principle of the minimization of surface or elastic energy. Lagrangean, Level-set and Phase-field approaches are well-known computational techniques for approximation of moving interfaces.

The goal of this mini-symposium is to discuss recent computational advances in solving moving free boundary problems, as adaptive high resolution finite element/ finite volume/finite difference solutions on general grids, tangential stabilization of Lagrangean algorithms for evolving curves and surfaces, and other issues important from modeling, implementation and simulation point of view, as well as practical applications where moving interfaces arise.

Evolving curves and sufaces in 2D and 3D image segmentation. **Karol Mikula** (Slovak University of Technology Bratislava, Slovakia) IC/MT2646/025

Evolving curves and surfaces are extensively used in applied sciences and engineering nowadays. In this talk we discuss a Lagrangean and Level-set approaches to solution of the corresponding geometric partial differential equations and the application of the computational methods to 2D and 3D image segmentation problems. In a detail we present semi-implicit complementary volume numerical scheme for solving Riemannian mean curvature flow of graphs and level sets applied to 2D and 3D image segmentation, edge detection, missing boundary completion and subjective contour extraction. We discuss level-set models leading to mean curvature driven image segmentation and outline basic advantages of the so-called subjective surface method given by the solution of the level-set equation

$$u_t = \sqrt{\varepsilon^2 + |\nabla u|^2}\nabla.\left(g(|G * \nabla I^0|)\frac{\nabla u}{\sqrt{\varepsilon^2 + |\nabla u|^2}}\right), \quad (1)$$

where g is nonincreasing (so called Perona-Malik) function, $\varepsilon > 0$ and $G * \nabla I^0$ is a smoothed gradient of the segmented image. We present stability and experimental convergence properties of the method on nontrivial examples of exact solutions and discuss computational results related to biological and medical image segmentation. The given results represent a joined works with Daniel Ševčovič and with S. Corsaro, A. Sarti and F. Sgallari.

Geometrical image segmentation by the Allen–Cahn equation. **Michal Beneš** (Czech Technical University, Prague, Czech Republic) IC/MT3057/025

We present an algorithm of pattern recovery (image segmentation) based on the numerical solution of the Allen-Cahn equation. The approach is usually understood as a regularization of the level-set motion by mean curvature where we impose a special forcing term which lets the initial level set closely surround the pattern of interest. We show basic computational features of the algorithm and demonstrate its function on several artificial as well as real examples.

Inverse problem in seismic imaging. **Maria Cameron** (University of California, Berkeley, USA), Andre Garon (École Polytechnique de Montréal, Canada), James Sethian (University of California, Berkeley, USA) IC/MT2839/025

Imaging of earth regions with nonhorisontal subsurface structures and laterally varying sound speed (seismic velocity) is very difficult. Time migration is a robust and efficient type of seismic imaging which does not require the knowledge of seismic velocities. However, it is adequate only for regions with mild lateral velocity variation. Moreover, time migrated images are obtained in somewhat unintuitive time coordinates. Depth migration is a type of seismic imaging which is adequate for regions with arbitrary lateral velocity variation and produces images in regular Cartesian coordinates. However, its implementation requires knowledge of seismic velocity.

Time migration has an additional output: migration velocities given in time coordinates. The goal of this work is to build an efficient algorithm to:

(a) estimate seismic velocities from migration velocities (then one can use these seismic velocities for obtaining depth migrated earth images);
(b) convert the time migrated images directly to regular Cartesian coordinates.

We established theoretical relations between migration velocities and seismic velocities in 2D and 3D using paraxial ray tracing theory. We formulated an inverse problem of finding seismic velocities from migration velocities and developed two numerical approaches for solving it. These approaches include Dijkstra-like Hamilton–Jacobi solvers for first arrival Eikonal equations and techniques for data smoothing. The outputs of our algorithms are seismic velocities and transition matrices from time coordinates to regular Cartesian coordinates. We tested these approaches on synthetic data examples and applied them to a field data example. We demonstrated that our algorithms give a significantly better estimate of seismic velocities than the Dix inversion which is the standard approach.

Numerical simulation of non-viscous liquid pinch off using a coupled level set-boundary integral method. **Maria Garzon** (Universidad de Oviedo, Spain), James Sethian (University of California, Berkeley, USA) IC/CT4944/025

The pinch off of an inviscid fluid column is described using a potential flow model with capillary forces. The interface velocity is obtained via a Galerkin boundary integral method for the 3D axisymmetric Laplace equation, whereas the interface location and the velocity potential on the free boundary are both approximated using level set type techniques on a fixed domain. The algorithm is validated computing the Rayleigh Taylor instability for liquid columns which provides an analytical solution for short times. The simulations have been continued in time and the algorithm is capable to handle pinch-off and after pinch-off events.

Advances in advancing interfaces: visco-elastic jets and semiconductor manufacturing. **James Sethian** (University of California, Berkeley, USA) IC/MT3065/025

We will describe new applications of interface techniques to problems in manufacturing. In viscoelastic two-phase flow, which is part of pigment-based dyes in ink jet plotters, drug delivery systems, and manufacturing of high resolution display devices, we discuss algorithms based on a combined level set second order projection method for viscoelastic flows with high Weissenberg numbers, showing the effects of viscoelasticity on droplet ejection and dynamics. In semiconductor manufacturing, we discuss problems in superconformal electrodeposition, involving metallization transport and concentration diffusion.

Tangentially stabilized algorithms for evolving curves. **Daniel Ševčovič** (Comenius University, Slovakia) IC/MT1602/025

We study evolution of plane curves satisfying the geometric equation $v = \beta(x, \nu, k, k_{ss})$ where v is the normal velocity, k and ν are the curvature and tangential angle of a plane curve $\Gamma \subset R^2$ at a point $x \in \Gamma$. We follow the so-called direct approach in order to derive a governing system of partial differential equations for the curvature, tangential angle, local length and position vector of the curve. These equations include a nontrivial tangential velocity functional yielding a uniform redistribution of grid points and thus preventing numerically computed solutions from forming various instabilities. We discretize the governing system in order to find a numerical solution for 2D isotropic and anisotropic plane curve evolution, interface motions in thermomechanics and medical image segmentation problems. This is a joint work with K.Mikula. Recent preprints and papers on this topic are available at www.iam.fmph.uniba.sk/institute/sevcovic

On the parametric finite-element approximation of evolving hypersurfaces in $\mathbb{R}^3$. **Robert Nürnberg** (Imperial College London, UK), John Barrett (Imperial College London, UK), Harald Garcke (Universität Regensburg, Germany) IC/MT1567/025

We present a variational formulation of motion by minus the Laplacian of curvature and mean curvature flow, as well as related second and fourth order flows of a closed hypersurface in $\mathbb{R}^3$. On introducing a parametric finite element approximation, we prove stability bounds and compare our scheme with existing approaches. The presented scheme has very good properties with respect to the distribution of mesh points and, if applicable, volume conservation.

Flux-based level set method: finite-volume method for evolving interfaces. **Peter Frolkovič** (Universität Heidelberg, Germany) IC/MT3045/025

The flux-based level set method is a finite volume method for solving an evolving interface implicitly described by a level set function [1]. The motion can be defined by an external passive transport and by a velocity given in the normal direction to the interface that can depend also on the mean curvature.

The level set equation is reformulated to a divergent form with a source term. The advective part is solved using high-resolution flux-based finite volume method [2] that is consistent on unstructured grids and second order accurate for smooth exact solutions. The numerical scheme for the advection is explicit, and the standard CFL restriction on time steps can be removed by using a recursive distribution of fluxes, the so called flux-based method of characteristics [3].

The parabolic part is solved using semi-implicit vertex-centred finite volume method (control volume or co-volume method) that has no restriction on time steps due to stability reasons. The combination of both methods defines the flux-based level set method. The method can be implemented by relatively

small changes to existing codes of finite volume methods for convection-diffusion equations.

Several examples will be given that illustrates the properties of the flux-based level set method like the consistency on locally adapted unstructured grids, second order accuracy for smooth solutions, the first order accuracy (approached from above) in more involved cases, a good behaviour even for largely distorted distance functions, and so on. The presented applications will include the modelling of convection-diffusion in two-phase flows with mass transfer through the interface, the problem of sail-boat distance, and others. The simulations are realized using the free software UG (Unstructured Grids) and the Matlab.

IC/MP150/025: Time integration of evolution equations.

Organiser: Alexander Ostermann (Universität Innsbruck, Austria)
Co-organiser: Mechthild Thalhammer (Universität Innsbruck, Austria)

Nonlinear evolution equations are fundamental in the description of complex dynamical processes. For the solution of realistic models, due to their complex and possibly chaotic nature, it is indispensable to utilise advanced numerical methods. The main topics of this minisymposium are: geometric integrators, exponential integrators and splitting methods.

In many situations, to obtain more specific information on physically relevant behaviour, it is essential that the numerical method preserves structural properties of the underlying problem. This includes conservation of energy and momentum, positivity, and multi-symplectic structures. In the last years, such geometric integration methods have received a lot of interest.

In connection with structure-preserving time integration methods, exponential integrators are attracting much interest. In contrast to standard integrators, they allow the use of large time-steps for oscillatory problems. Moreover, they have excellent stability properties.

Another topic that will be covered by our minisymposium is the numerical analysis of splitting methods. For problems in many space dimensions, such methods are widely used. Their error behaviour, however, is far from being well understood.

Runge–Kutta convolution quadrature methods for well posed equations with memory. **César Palencia** (Universidad de Valladolid, Spain), Mari Paz Calvo Cabrero (Universidad de Valladolid, Spain), Eduardo Cuesta (Universidad de Valladolid, Spain) IC/MT4033/025

Runge–Kutta based convolution quadrature methods for abstract, well-posed, linear, and homogeneous Volterra equations, non necessarily of sectorial type, are developed. A general representation of the numerical solution in terms of the continuous one is given. The error and stability analysis is based on this representation, which also shows that the numerical solution inherits some interesting qualitative properties, such as positivity, of the exact solution. Numerical illustrations are provided.

Exponential integrators for applications in relativistic laser plasma dynamics. **Marlis Hochbruck** (Universität Düsseldorf, Germany), Julia Schweitzer (Universität Düsseldorf, Germany) IC/MT4013/025

A mathematical model of the interaction of relativistically intense electromagnetic waves with a plasma leads to a system of coupled nonlinear Klein-Gordon equations. The quantities of interest are the vector potential of the laser pulse and the electron density of the plasma. Numerical difficulties of this problem arise because of the oscillatory nature of the solution both in time and space and because of the interest in long-time simulations.

The standard approach for solving these equations numerically is to apply a pseudospectral discretization in space using FFT and to integrate in time with the Störmer/Verlet scheme. In this talk we present an alternative which results in the constructing of a new exponential integrator for this particular application.

This is joint work with Ch. Karle, E.W. Laedke, and K.H. Spatschek, Institute for Theoretical Physics, Heinrich-Heine Universität Düsseldorf.

Understanding the leapfrog scheme via trigonometric integrators. **Christian Lubich** (Universität Tübingen, Germany) IC/MT4986/025

We present results on the long-time near-conservation of energy, momentum and actions in full discretizations of semilinear wave equations in the weakly nonlinear regime. Here we consider pseudospectral discretization in space and the standard leapfrog discretization in time. The results come about by the technique of modulated Fourier expansions and by interpreting the leapfrog method as a trigonometric integrator with modified frequencies. The conservation properties differ markedly from those for standard Runge-Kutta methods.

David Cohen, Ernst Hairer, Christian Lubich, Conservation of energy, momentum and actions in numerical discretizations of nonlinear wave equations, Report, April 2007.

Exponential operator splitting for time-dependent Schrödinger equations. **Mechthild Thalhammer** (Universität Innsbruck, Austria) IC/MT3996/025

In this talk, we consider evolution equations involving an unbounded linear operator. The focus is on problems related to time-dependent Schrödinger equations or spatial discretisations thereof. Our concern is to analyse the convergence and stability behaviour of high-order exponential operator splitting methods. The theoretical error bounds are illustrated by numerical examples.

IC/MP231/025: Numerical methods for option pricing.

Organiser: Olivier Pironneau (Université Paris VI, France)
Co-organiser: Jari Toivanen (Stanford University, USA)

This minisymposium considers deterministic numerical methods for option pricing based on partial (possibly integro) differential equations. Models for underlying assets including jumps lead to non local integral terms. The numerical treatment of these terms is challenging already for low dimensional models. Levy Copulas offer a way to generalize jump models for higher dimensions. When option price depends on more than three factors traditional methods for PDEs are not efficient. Sparse grids give a way to discretize these higher dimensional problems with a feasible amount of unknowns leading to usable methods. For many European options it is possible to derive analytical formulas, but American options lead to nonlinear problems which have to be priced numerically. Lagrange multiplier approach offers a theoretically sound and computationally efficient way to price American options. In order to use the option pricing model in practice, they have to be calibrated using market data, that is, their parameters have to tuned so that that they give prices which match market prices. These calibration problems are typically computationally very challenging and they require efficient methods. All these above mentioned topics are considered in this minisymposium.

Sparse-grid methods for the fast evaluation of financial derivatives. **Michael Griebel** (Universität Bonn, Germany) IC/MT1334/025

We present sparse grid quadrature methods for the evaluation of options and other financial instruments. They are, as MC and QMC methods, able to cope with high(er) dimensional problems. In constrast to MC or QMC these techniques exploit any additional smoothness of the integrand. We consider various applications from finance and discuss the advantages of the sparse grid technique for different financial instruments.

Solving the forward Kolmogorov equation for options in 2D. **Olivier Pironneau** (Université Paris VI, France), Nicolas Lantos (Université Pierre et Marie Curie, France) IC/MT3935/025

Pricing complex options such as baskets or those modeled by stochastic volatilities may involve solving multi-dimensional Black-Scholes like equations. Computing several such options at once can be a numerical challenge. We investigate here the Kolmogorov equation and Dupire or “pre-Dupire" equations to solve the problem faster and validate the approach numerically. The heart of the method is to use the adjoint of the PDE of the option at the discrete level and to use discrete duality identities to obtain Dupre-like relations. The method works on most linear models. Results will be given for basket options and Heston stochastic volatility models and others.

Lagrange-multiplier approach for american options. **Kazufumi Ito** (North Carolina State University, USA) IC/MT2385/025

A general class of parabolic variational inequalities is discussed and the existence and uniqueness of the strong and weak solution are established. Our approach is based on the Lagrange multiplier treatment and the solution is defined as a a unique asymptotic limit of solutions to a family of nonlinear parabolic equations as regularization parameter tending to the infinity. The monotonicity results of the regularized solutions and convergence rate are established. The results are applied to the Black-Sholes model for American option. The case of the bilateral constraint is also treated. A numerical result for the Black-Sholes model is presented and demonstrates a practical usage and interpretation of our results.

High-dimensional PDE methods applied to option pricing. **Yves Achdou** (Université Paris VII, France), Olivier Pironneau (Université Paris VI, France), David Pommier (BNP Paribas France) IC/MT3936/025

Recent developments have shown that it may be possible to use deterministic Galerkin methods or grid based methods for elliptic or parabolic problems in dimension d, for $4 \leq d \leq 20$: these methods are based either on sparse grids [1] or on sparse tensor product approximation spaces [2,3].
Sparse grids were introduced by Zenger [4] in order to reduce the number of degrees of freedom of discrete methods for partial differential equations. Standard piecewise linear approximations need $O(h^{-d})$ degrees of freedom, (h is the mesh step), and produce errors of the order of $O(h^2)$. The piecewise-d-linear sparse grid approximation requires only $O\left(h^{-1}|\log h|^{d-1}\right)$ degrees of freedom, while the error is $O\left(h^2|\log h|^{d-1}\right)$.
We discuss the use of these methods for the numerical solution of diffusion or advection-diffusion problems introduced in option pricing. We consider contracts on multi-assets and European vanilla contract in multifactor stochastic volatility models.

IC/MP231/025: Numerical methods for option pricing. #2

Organiser: Olivier Pironneau (Université Paris VI, France)
Co-organiser: Jari Toivanen (Stanford University, USA)

(For abstract, see session #1 above.)

Computational methods for Levy models in finance. **Christoph Schwab** (ETH Zürich, Switzerland) IC/MT2132/025

We report on our development of deterministic computational techniques for financial models with jumps. Such models emerged in the past decade as generalizations of the Black-Scholes models, s tarting with the work of Madan and Seneta in 1990. Our approach is based on Galerkin discretizat ion of the process' infinitesimal generator resp. Dirichlet form in a multiscale basis. The meth ods allow to value single and multiperiod contracts, european, american or exotic, on single und erlyings or baskets. Before illustrating the techniques by a number of case studies, among other s for Levy copula dependence models, stochastic volatility models and continuous time GARCH mode ls, we explain the computational techniques and hint at their mathematical background. Determini stic computation of certain optimal hedging strategies by these methods will also be addressed. Joint work of the CMQF group in the Seminar for Applied Mathematics, ETH.

A fast FFT-based method for pricing early-exercise options under Levy processes. **Cornelis Oosterlee** (TU Delft, The Netherlands) IC/MT2126/025

A fast and accurate method for pricing early exercise and certain exotic options in computational finance is presented in this paper. The method is based on a quadrature technique and relies heavily on Fourier transformations. The main idea is to reformulate the well-known risk-neutral valuation formula by recognising that it is a convolution. The resulting convolution is dealt with numerically by using the Fast Fourier Transform (FFT). This novel pricing method, which we dub the Convolution method, CONV method for short, is applicable to a wide variety of payoffs and only requires the knowledge of the characteristic function of the model. As such the method is applicable within exponentially Lévy models, including the exponentially affine jump-diffusion models. For an M-times exercisable Bermudan option, the overall complexity is $O(MN\log(N))$ with N grid points used to discretise the price of the underlying asset. It is shown how to price American options efficiently by applying Richardson extrapolation to the prices of Bermudan options.

A fast and accurate method in pricing early-exercise options under Levy processes. **Fang Fang** (TU Delft, The Netherlands) IC/MT2216/025

When valuing and risk-managing exotic derivatives, practitioners demand fast and accurate prices and sensitivities. Since the models being used in practice are becoming increasingly more complex, efficient methods have to be developed to cope with such models. Aside from non-standard exotic derivatives, plain vanilla options in many stock markets are actually of the American type. As any pricing and risk management system has to be able to calibrate to these plain vanilla options, it is of the utmost importance to be able to value these American options quickly and accurately. A fast and accurate method in pricing early exercise options is developed in this paper, and it is applicable to exponentially affine jump-diffusion models, exponential Lévy models, and variants hereof. In the remainder we will refer to this class of models as the exponentially affine Lévy class. The method relies heavily on the fast Fourier Transform (FFT) algorithm. Early FFT based solution methods were mainly developed in pricing European options, see Heston (1993) and Carr and Madan (1999). Andricopoulos et al. (2002) introduced the quadrature method QUAD, which can be used to value a variety of options with exotic features. It assumes the transition density of the underlying asset is available in closed-form. As in some models only the characteristic function is known, O'Sullivan (2004) combined the early Fourier transform methods with the QUAD method and developed his QUAD-FFT method. The overall computational complexity of his approach is $O(MN^2)$ with M denoting the number of exercise dates and N being the number of points in the asset dimension. This strain of the literature does not seem to have picked up on unpublished work by Reiner (2000), who recognized that, at least for the Black-Scholes model, an option price can be seen as a convolution of the payoff function and the probability density function. This result is well-established for European payoffs, though Reiner demonstrates that the same idea can be used for Bermudan options as well as for weakly path-dependent options such as discretely sampled Asian options, discretely monitored lookbacks and barriers or cliquets. In our work we combine Reiner's ideas with the work of Carr and Madan into what we call the CONV method, which stands for convolution. It utilizes the power of the FFT algorithm as much as possible so that an overall complexity of $O(MN\log(N))$ is achieved.

The basic idea of the CONV method is to start from the risk-neutral valuation formula,

$$\begin{aligned} C(t,x) &= e^{-r\Delta t}\mathbb{E}^{\mathbb{Q}}_{t,S_t}\left[V(t+\Delta t,y)\right] \\ &= e^{-r\Delta t}\int_{-\infty}^{\infty} V(t+\Delta t,y)f(y|x)dy, \end{aligned} \tag{1}$$

where x and y denote the state variables at time t and $t+\Delta t$, respectively, $C(t,x)$ the continuation value of the option at time t, $V(t+\Delta t,y)$ the value of the option at time $t+\Delta t$, $\mathbb{E}^{\mathbb{Q}}_{t,S_t}$ the expectation operator under risk-neutral measure $\mathbb{Q}$, and $f(y|x)$ the conditional density function of y at $t+\Delta t$ given x at t. If the underlying models satisfy $f(y|x)=f(y-x)$, which is the case for e.g. the previously mentioned one-dimensional exponentially affine Lévy models, (1) is thus equivalent to

$$C(t,x) = e^{-r\Delta t}\int_{-\infty}^{\infty} V(t+\Delta t,x+z)f(z)dz, \tag{2}$$

where $z=y-x$. Damping (2) with $e^{\alpha x}$ and then taking the Fourier transform, we have

$$\begin{aligned} \hat{C}(t,\omega) &= \int_{-\infty}^{\infty} e^{i\omega x}\int_{-\infty}^{\infty} e^{\alpha x}V(t+\Delta t,x+z)f(z)dzdx, \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} e^{i(\omega-i\alpha)(y-z)}V(t+\Delta t,y)dy\,f(z)dz, \\ &= \underbrace{\int_{-\infty}^{\infty} e^{i(\omega-i\alpha)y}V(t+\Delta t,y)dy}_{\hat{V}_{t+\Delta t}(\omega-i\alpha)}\cdot\underbrace{\int_{-\infty}^{\infty} e^{i(-\omega+i\alpha)z}f(z)dz}_{\phi(-\omega+i\alpha)}, \end{aligned} \tag{3}$$

where $\phi(v)$ denotes the characteristic function of the density $f(z)$. $C(t,x)$ can be recovered by the inverse Fourier transform on (3). When pricing Bermudan options, which will be the focus of this talk, we subsequently apply the early exercise condition:

$$V(t,x)=\max\left(C(t,x),\ \text{payoff}\right), \tag{4}$$

in order to obtain the option value at time t.

The numerical results will include both CPU times and error/convergence measurements in pricing European, Bermandan and American options under geometric Brownian motion (GBM), the Variance Gamma (VG), and the CGMY model, respectively. As an example, to value a 10-time exercisable Bermudan option (under any of the three models), the method takes 0.03 seconds and returns with an error of order 10^{-5}, and a consistent pointwise second-order convergence in log-stock grid width is observed.

Work in collaboration with R. Lord (Modeling and Research, Rabobank International, Utrecht, The Netherlands), C.W. Oosterlee (Delft University of Technology, Delft Institute of Applied Mathematics, Delft, the Netherlands), and F. Bervoets (Modeling and Research, Rabobank International, Utrecht, The Netherlands).

Numerical valuation of options under Kou's model. **Jari Toivanen** (Stanford University, USA) IC/MT972/025

Under Kou's jump-diffusion model the value of a European option satisfies a partial integro-differential equation. Implicit finite difference discretizations are performed on nonuniform space-time grids. For the evalution of the integral term fast recursion formulas are derived leading to optimal computational cost per time step and second-order accuracy in space.

For European options the resulting dense linear problems are solved using a stationary iterative method which requires only a few iterations. For the treatment of the early exercise constraint of American options an operator splitting method and a penalty method are considered.

Numerical experiments demonstrate that accurate option prices can be obtained in a few milliseconds on a PC.

IC/MP213/025: Multiscale porous media: discretizations.

Organiser: Mary Wheeler (University of Texas at Austin, USA)
Co-organiser: Ivan Graham (University of Bath, UK)
Co-organiser: Hector Klie (University of Texas at Austin, USA)

Multiphase flow, transport, and reaction in porous media have important applications in petroleum reservoir engineering and in groundwater flow. These often involve multiphase multiphysics processes across multiple temporal and spatial scales. This minisymposium delves into the state-of-the-art multiscale and physics-preserving numerical algorithms for such porous media phenomena. It is linked to the two other minisymposia: "Multiscale porous media: solvers" and "Multiscale porous media: applications".

Multiscale discretizations for flow, transport and mechanics in porous media. **Mary Wheeler** (University of Texas at Austin, USA) IC/MT3365/025

A fundamental difficulty in understanding and predicting large-scale fluid movements in porous media is that these movements depend upon phenomena that occur on small scales in space and/or time. The differences in scale can be staggering. Aquifers and reservoirs extend for thousands of meters, while their transport properties can vary across centimeters, reflecting the depositional and diagenetic processes that formed the rocks. In turn, transport properties depend on the distribution, correlation and connectivity of micron-sized geometric features, such as pore throats, and on molecular chemical reactions. Seepage and even pumped velocities can be extremely small as compared to the rates of phase changes and chemical reactions. The coupling of flow simulation with mechanical deformations is also important in addressing the response of reservoirs located in structurally weak geologic formations.

We will focus on the mortar mixed finite element method (MMFE) that was first introduced by Arbogast, Cowsar, Wheeler, and Yotov for single phase flow, later extended to multiphase flow by Lu, Pesyznska, Wheeler, and Yotov, and more recently extended, by Wheeler, to transport. The MMFE method is quite general in that it allows for non-matching interfaces and the coupling of different physical processes in a single simulation. This is achieved by decomposing the physical domain into a series of subdomains (blocks) and using independently constructed numerical grids and possibly different discretization techniques in each block. Physically meaningful matching conditions are imposed on block interfaces in a numerically stable and accurate way using mortar finite element spaces. The mortar approach can be viewed as a subgrid or two-scale approach. Moreover, the use of mortars allows one to couple MMFE and discontinuous Galerkin approximations in adjacent subdomains. In this presentation we will discuss theoretical *a priori* and *a posteriori* results, and computational results will be presented.

Well modeling in the multi-scale finite-volume context based on correction functions. **Patrick Jenny** (ETH Zürich, Switzerland) IC/MT1339/025

A numerical reservoir simulator must accurately resolve the length and time scales associated with the complex interactions that take place when several species (components) are transported via multiple fluid phases through a natural geologic formation of large extent. Natural geologic formations often display high variability, complex patterns of spatial correlation, and span a wide spectrum of length scales. For example, the spatial variation of permeability, which is of central importance here, can be quite significant over relatively small distances. The push for more reliable predictions of flow performance has lead to enormous growth in both the geometric complexity and level of detail incorporated in reservoir characterization models. Because of the complex multi-scale nature of the properties, which usually appear as coefficients in the governing equations, modeling of flow in heterogeneous porous media is an ideal target of multi-scale solution techniques. Recently, a multi-scale finite-volume (MSFV) method [1], which employs basis functions, was developed. Since the basis functions are local numerical solutions, they are able to capture the local fine-scale permeability distribution effectively and allow very accurate pressure interpolations between the coarse-grid nodes. For a large variety of difficult multi-phase flow test cases it was shown that the MSFV solutions are in excellent agreement with the corresponding fine-scale results. Later, the method was extended for compressible [2] and gravity driven [3] flow and a well model was incorporated [4]. Here, an alternative way to deal with wells in the MSFV framework is introduced. Opposed to the previously published method, no well domains need to be specified, however, the new approach requires to iterate.

Combining finite volumes and finite elements for non-matching grids. **Martin Vohralík** (Université Pierre et Marie Curie (Paris 6), France) IC/MT1215/025

We propose and analyze a numerical scheme for nonlinear degenerate parabolic convection–diffusion–reaction equations in two or three space dimensions. We use the cell-centered finite volume method on a given grid, which can be nonmatching and can contain nonconvex elements, for all terms except of the diffusion one, which is discretized by the finite element method on a dual conforming simplicial mesh. In this way, the discrete solution is naturally continuous across the interfaces without introducing any supplementary matching conditions as e.g. in the mortar method. The resulting scheme allows to work with inhomogeneous and anisotropic diffusion tensors, is robust, efficient, locally conservative, and stabilized by only adding the minimal numerical diffusion necessary. We prove its convergence in the degenerate parabolic case using *a priori* estimates and the Kolmogorov relative compactness theorem. We then derive *a posteriori* error estimates in the linear case. They are of residual type and we establish them in the energy norm. We prove that they are both reliable and efficient, giving upper and lower bounds on the error, and semi-robust in the sense that the efficiency constant only depends on local variations in the coefficients and becomes optimal as the local Péclet number gets sufficiently small. They are in particular fully computable (all occurring constants are evaluated explicitly), so that they can serve both as indicators for adaptive refinement or for the actual control of the error. We finally illustrate the above results on numerical simulations of the problem of transport of contaminants in porous media.

This work was done in collaboration with Robert Eymard, Université de Marne-la-Vallée, and Danielle Hilhorst, Université de Paris-Sud and CNRS, France.

Mortar methods as multiscale methods. **Ivan Yotov** (University of Pittsburgh, USA), Mary Wheeler (University of Texas at Austin, USA) IC/MT1782/025

We discuss the relationship between mortar finite element methods and multiscale finite element methods. The latter represent the solution as a sum of a coarse scale and a fine scale (subgrid) component and require solving local fine scale problems to compute the multiscale basis functions. Mortar methods with coarse mortar spaces also resolve the solution on the fine scale on each subdomain, but impose continuity conditions on the coarse scale. A domain decomposition algorithm for the algebraic problem requires solving fine scale local problems on each interface iteration. We study the accuracy and efficiency of the mortar multiscale approach in the context of the multipoint flux mixed finite element method.

IC/MP196/026: Challenges for the accurate solution of Laplace eigenvalue and scattering problems.

Organiser: Timo Betcke (University of Manchester, UK)
Co-organiser: Lehel Banjai (Universität Zürich, Switzerland)

Two fundamental problems of wave computations are the Laplace eigenvalue and the scattering problem. Although often different techniques are applied for these two problems the challenges for the solution of them are very similar, such as the right choice of basis functions for an accurate representation of the solution or high frequency computations, which can be regarded as multiscale problems. In this minisymposium we bring together people who are working on the eigenvalue problem and people who are working on the scattering problem to present these challenges and novel solution techniques for them. The presentations involve applications in the quantum physics of chaotic systems, electromagnetic scattering, error estimates and the design of good approximation bases for these problems.

Approximation theory and bases for the Helmholtz equation. **Timo Betcke** (University of Manchester, UK), Alex Barnett (Dartmouth College, USA) IC/MT1483/026

Solutions of the Helmholtz equation in 2D are closely related to holomorphic functions in the complex plane via the so called Vekua operator. We use this theory to review the application of results from complex approximation theory to the design of fast converging approximation bases for the Helmholtz equation. But not only theoretical convergence rates are important in the design of bases. An equally important question is what bases allow well-conditioned representations of solutions of the Helmholtz equation. We discuss results to this effect and present examples involving the eigenvalue problem and the boundary value problem.

The scaling method for high-frequency eigenvalue calculations. **Alex Barnett** (Dartmouth College, USA), Timo Betcke (University of Manchester, UK) IC/MT2451/026

Eigenmode problems appear in acoustics, electromagnetics, and modern applications such as the design of micro-cavity dielectric lasers. When the wavelength is much shorter than the cavity size this becomes a multiscale problem, and boundary methods are needed. I will present an accelerated variant of the method of particular solutions (MPS, a global bassis approximation method) which allows $O(k)$ modes to be calculated in the effort usually required for a single mode, k being the wavenumber. This removes the need for expensive root-searches along the wavenumber axis. Perturbative analysis of the MPS has also led to new eigenvalue error bounds which are $O(k)$ tighter than the classical bounds of Moler-Payne. Finally I will present some work on applying a generalized MPS to locate complex resonance poles of 2D dielectric optical cavities, which connects directly to scattering problems.

High-frequency electromagnetic scattering by convex polygons. **Stephen Langdon** (University of Reading, UK), Simon Chandler-Wilde (University of Reading, UK) IC/MT1768/026

The authors have recently developed a boundary element method for problems of acoustic scattering by sound soft convex polygons for which, by including in the approximation space products of piecewise polynomials supported on a graded mesh with plane wave basis functions, it has been possible to establish a computational cost that depends only logarithmically on the frequency of the incident wave. In this talk we consider the extension of these ideas to electromagnetic scattering problems which in two dimensions can be formulated as Helmholtz problems with transmission boundary conditions. The transmission boundary condition necessitates the solution of the Helmholtz problem on an interior as well as an exterior domain, and thus the problem is significantly more complicated than the corresponding acoustic scattering problem. Some of the issues involved are closely related to those in the Laplace eigenvalue problem.

The effect of a high wave number on numerical schemes for the Helmholtz problem. **Lehel Banjai** (Universität Zürich, Switzerland), Stefan Sauter (Universität Zürich, Switzerland) IC/MT2124/026

The talk will introduce the well-known pollution effect in the FEM when applied to high-frequency Helmholtz problems. We mention some possible ways to reduce the pollution errors but also the fact that pollution in FEM in dimensions larger than 1 is unavoidable.
BEM seems to be more robust in this aspect, as has been noticed in numerics for some time. However, until recently, few theoretical results have been available that explain this experimentally noted behaviour. For scattering by some special domains (sphere, plane), we give the complete analysis of the Galerkin method. Further, we summarize the known wave number explicit estimates for more general domains.

IC/MP71/026: High-order compact schemes for partial differential equations.

Organiser: Murli Gupta (The George Washington University, USA)

This minisymposium will bring together researchers who have been developing, and testing, high accuracy compact finite difference schemes for the solution of a variety of partial differential equations. Emphasis will be on the use of highly efficient solution techniques such as multigrid and parallel computations, and applications to fluid flow problems. We will invite researchers doing theoretical as well as computational analysis. One of the aims of this minisymposium is to compare the progress made since ICIAM 2003 in Sydney.

An efficient compact formulation for the transient Navier–Stokes equations in biharmonic form. **Jiten Kalita** (IIT Guwahati, India), Murli Gupta (The George Washington University, USA) IC/MT2492/026

We recently proposed a new paradigm for solving the steady-state two-dimensional (2D) Navier- Stokes (N-S) equations using a streamfunction- velocity (ψ-v) formulation. This formulation was shown to avoid the difficulties associated with the traditional formulations (primitive variables, and streamfunction-vorticity formulations). The new formulation was found to be second order accurate, and was found to yield accurate solutions of a number of fluid flow problems.

In this paper, we propose a second order time and space accurate, implicit, unconditionally stable scheme on compact uniform grids for the unsteady incompressible N-S equations based upon the ψ-v formulation. The scheme is used to solve several fluid flow problems, including the flow decayed by viscosity problem, a problem with non-homogeneous source term, both of which have analytical solutions, and, the lid-driven square cavity problem. For the first two problems, our coarse grid transient solutions for high Reynolds numbers (Re) are extremely close to the analytical ones. For the cavity problem, our time-marching steady-state solutions up to $Re = 7500$ are excellent match with established numerical results, and for $Re = 10000$, our study asserts that the asymptotic stable solution is mainly periodic as had been found by some recent studies.

Recent advancements to the generalized high-order compact scheme. **William Spotz** (Sandia National Laboratories, USA) IC/MT3371/026

The generalized high-order compact scheme (GHOC) generalizes the high-order compact (HOC) scheme by applying it to unstructured grids. This is done in a manner analogous to the generalized finite difference method (GFDM), which generates a small linear system for each grid point and its surrounding stencil based on Taylor Series expansions. Numerically inverting this small system yields finite difference approximations to various derivatives at the given point. In the GHOC scheme, this linear system is expanded by including derivatives of the governing equation, and yields higher-order approximations to more derivatives at the central grid point of the stencil. This approach also greatly simplifies the derivation of HOC schemes, as much of the error-prone algebra is now replaced by the numerical inversion of a small linear system. It also provides a elegant framework for handling more complex types of boundary conditions. At the previous ICIAM, I presented analysis and results for the GHOC scheme in 1D. More recent advancements include explorations in 2D, issues regarding reproducing classic HOC results, and more sophisticated error analysis.

On the choice of initial conditions of difference schemes for parabolic equations. **Murli Gupta** (The George Washington University, USA), Manana Mirianashvili (Georgian Academy of Sciences), Givi Berikelashvili (A.Razmadze Mathematical Institute, Georgia) IC/MT3769/026

As a model problem we consider the first initial-boundary value problem for linear second-order parabolic equations with constant coefficients in the domain $Q = \Omega\times(0,T] = (0,1)^2\times(0,T]$:

$$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} - au + f(x,y,t) \ \text{ in } \ Q$$
$$u(x,y,0) = u_0(x,y) \ \text{ on } \ \Omega, \quad u(x,y,t) = 0 \ \text{ on } \ \partial\Omega\times[0,T].$$

We suppose that the generalized solution of this belongs to the anisotropic Sobolev space $W_2^{s,s/2}(Q)$, $s > 1$.

In the case of difference schemes constructed for this problem, when obtaining convergence rate estimate, compatible with smoothness of the solution, various authors make an assumption that the solution of the problem can be extended to the domain $(-d, 1+d)^2 \times (-d, T]$, with $d > 0$, preserving the Sobolev class.

Investigations have shown that if instead of an exact function $u_0(x,y)$, its approximation (using the above) is taken as an initial condition, then this restriction can be removed.

A high-order alternating direction implicit (ADI) difference scheme is constructed in the paper for which the convergence rate estimate

$$\|\tilde{u} - u\|_{L_2(Q_{h,\tau})} \le C(h^s + \tau^{s/2})\|u\|_{W_2^{s,s/2}(Q)}, \quad s \in (2,4]$$

is obtained. Here $\tilde{u}$ is a solution of the difference scheme, $Q_{h,\tau}$ is a mesh in Q, C is a positive constant independent of h, τ and u, and h and τ are space and time steps respectively.

High-order ADI method for stream-function vorticity equations. **Samir Karaa** (Sultan Qaboos University, Oman) IC/MT3753/026

Many recent works have demonstrated the efficiency of high-order compact difference schemes on the streamfunction and vorticity formulation of 2-D incompressible Navier-Stokes equations. High order compact discretizations induce cross spatial derivatives which are treated explicitly in most ADI schemes. Recently, Karaa and Zhang proposed a fourth order ADI method for solving convection-diffusion problems efficiently. In this work, we extend this method to the solution of incompressible Navier-Stokes equations. Numerical results are obtained for the model problem of driven cavity flow and compared with other results available in the literature.

IC/MP205/026: FETI, balancing, and related hybrid domain-decomposition methods.

Organiser: Axel Klawonn (Universität Duisburg-Essen, Germany)
Co-organiser: Ulrich Langer (Universität Linz, Austria)
Co-organiser: Barbara Wohlmuth (Universität Stuttgart, Germany)

Domain decomposition methods are a successful approach for the solution of the often very large systems arising from the discretization of partial differential equations. The best algorithms from this class of methods are highly scalable on massively parallel computers.

Finite Element Tearing and Interconnecting (FETI) and Balancing Domain Decomposition methods are two related families of such iterative substructuring algorithms which are by now quite well-known. In this minsymposium we gather several active researchers in the field who are going to present their latest results on new theoretical developments, different discretizations and applications, and parallel scalability.

Coupled finite and boundary-element domain decomposition methods. **Olaf Steinbach** (TU Graz, Austria) IC/MT2969/026

Finite and boundary element methods often have complementary properties in different situations. Domain decomposition methods allow to use the discretization method which is the most appropriate one for the subdomain under consideration. The coupling is based on appropriate transmission conditions in which the Dirichlet to Neumann and the Neumann to Dirichlet map play an important role, respectively. Here we give a general overview on different formulations leading to coupled finite and boundary element methods. In general, we have to solve large scale systems of coupled finite and boundary element equations. The efficiency of iterative methods heavily depends on the availability of efficient preconditioners. We consider various solution strategies, in particular tearing and interconnecting methods, and provide appropriate precondi-

tioners resulting in asymptotically almost optimal solvers. This talk summarizes joint work with W. L. Wendland, G. Of, and U. Langer.

Coupled FETI/BETI solvers for nonlinear potential problems in unbounded domains. **Clemens Pechstein** (Universität Linz, Austria), Ulrich Langer (Universität Linz, Austria) IC/MT1828/026

This contribution deals with the numerical solution of nonlinear potential equations of the form $-\nabla \cdot [\nu(x,|\nabla u(x)|)\,\nabla u(x)] = f(x)$, for $x \in \mathbb{R}^d = \overline{\Omega} \cup \overline{\Omega}^c$, where Ω is open and bounded, and $\Omega^c := \mathbb{R}^d \setminus \overline{\Omega}$. Such equations arise e. g. in two-dimensional magnetic field computations. On the unbounded exterior domain Ω^c we assume that $f \equiv 0$ and $\nu \equiv \nu_0 = \text{const}$, and furthermore that $u(x)$ satisfies a suitable radiation condition for $|x| \to \infty$. We apply Newton's method to the nonlinear variational formulation and solve the linearized problems using a special coupled Finite and Boundary Element Tearing and Interconnecting (FETI/BETI) method. In order to get a good initial guess for Newton's iteration, we use the nested iteration strategy based on a hierarchy of nested grids. In case of a nonlinear coefficient, the spectrum of the corresponding subdomain Jacobi matrices may show high variation. In magnetostatic applications, this variation indeed appears in ferromagnetic materials, where the ratio between the largest and the smallest ocurring value of the reluctivity ν can be 10^3 and more. However, the local anisotropy is typically small and the coefficient field has some smoothness properties. We propose a special FETI/BETI preconditioner that shows only a weak dependence of the number of PCG iterations on the variation in our numerical experiments.

For a piecewise constant coefficient, the condition number of the preconditioned FETI/BETI system corresponding to a boundary value problem on Ω is known to be $\mathcal{O}((1+\log(\frac{H}{h}))^2)$, independent of the mesh size h, the maximal edge/face diameter H and possible jumps in the coefficient across subdomain interfaces. Including the exterior space Ω^c as a subdomain, we can show the same estimate if a primal coarse space is chosen accordingly to the FETI-DP variant.

Domain-decomposition multiscale methods for flow in porous media. **Mary Wheeler** (University of Texas at Austin, USA) IC/MT3849/026

A fundamental difficulty in understanding and predicting large-scale fluid movements in porous media is that these movements depend upon phenomena occuring on small scales in space and/or time. The differences in scale can be staggering. Aquifers and reservoirs extend for thousands of meters, while their transport properties can vary across centimeters, reflecting the depositional and diagenetic processes that formed the rocks. In turn, transport properties depend on the distribution, correlation and connectivity of micron sized geometric features such as pore throats, and on molecular chemical reactions. Seepage and even pumped velocities can be extremely small compared to the rates of phase changes and chemical reactions.

We will focus on the mortar methods which was first introduced by Arbogast, Cowsar, Wheeler, and Yotov for mixed finite element method (MFE) approximations for single phase flow and later extended to multiphase flow by Lu, Pesyznska, Wheeler, and Yotov. This method is quite general in that it allows for non-matching interfaces and the coupling of different physical processes in a single simulation. This is achieved by decomposing the physical domain into a series of subdomains (blocks) and using independently constructed numerical grids and possibly different discretization techniques in each block. Physically meaningful matching conditions are imposed on block interfaces in a numerically stable and accurate way using mortar finite element spaces. This domain decomposition approach can be viewed as a subgrid or two scale approach. Moreover, the use of mortars allows one to couple MFE and discontinuous Galerkin approximations in adjacent subdomains. In this presentation we will discuss theoretical *a priori* and *a posteriori* results and computational results will be presented.

Multilevel BDDC. **Bedřich Sousedík** (University of Colorado, USA), Jan Mandel (University of Colorado at Denver, USA), Clark Dohrmann (Sandia National Laboratories, USA) IC/MT3026/026

We present the formulation and condition number bounds for a multilevel version of the BDDC algorithm. The condition number bounds grows polylogarithmically with the ratio of the substructure sizes between levels, but they grow exponentially with the number of levels. Numerical results show that this may indeed occur.

The condition number bounds are based on an abstract multilevel algebraic theory suitable for nested substructuring methods.

Large-scale simulations of arterial walls: parallel solution strategies. **Oliver Rheinbach** (Universität Duisburg-Essen, Germany), Axel Klawonn (Universität Duisburg-Essen, Germany), Jörg Schröder (Universität Duisburg-Essen, Germany), Dominik Brands (Universität Duisburg-Essen, Germany) IC/MT3577/026

Nonoverlapping domain decomposition methods are fast parallel solvers for large equation systems arising from the discretization of partial differential equations. In this talk, dual iterative substructuring methods of the FETI-DP (Finite Element Tearing and Interconnecting Dual-Primal) type are described and applied to the biomechanical problem of elastic deformations of arterial walls. This problem poses various challenges to solver algorithms (i.e., nonlinearity, almost incompressibility, very large material jumps); e.g., when atherosclerotic plaques with calcifications are present, and anisotropy. Our goal is the developement of a method which performs robustly within this setting and still shows good scalability. The mechanical modeling is the focus of a companion talk by D. Brands.

Extending domain decomposition to problems with irregular subdomains. **Olof Widlund** (Courant Institute, NYU, USA) IC/MT3572/026

In the theory of iterative substructuring methods and certain other domain decomposition algorithms, each subdomain is typically assumed to be the union of a small set of coarse triangles or tetrahedra. Such an assumption is often unrealistic, in particular, if the subdomains are produced using mesh partitioner software. An extension of the theory requires that a number of technical tools be generalized. A survey will be given of recent results.

Optimal TOTAL FETI solver for 3D frictionless-contact problems. **Zdeněk Dostál** (TU Ostrava, Czech Republic) IC/MT3332/026

We shall first briefly review the FETI based domain decomposition methodology adapted to the solution of frictionless multibody contact problems in 3D. We use modification that we call TFETI (Total FETI) [1] which imposes prescribed displacements by Lagrange multipliers. As a result, we shall obtain a convex quadratic programming problem with a special inequality and equality constraints. The classical results concerning the solution of linear elliptic boundary value problems give that the condition number of the Hessian of the quadratic form is bounded independently on the discretization parameter h.

Then we shall present our algorithms for the solution of resulting quadratic programming problems. The unique feature of these algorithms is their capability to solve the class of quadratic programming problems with spectrum in a given positive interval in O(1) iterations. The algorithms enjoy the rate of convergence that is independent of conditioning of constraints and the results are valid even for linearly dependent equality constraints.

Finally we put together our results on approximation of variational inequalities and those on quadratic programming to develop algorithms for the solution of both coercive and semicoercive variational inequalities and show that the algorithms are scalable [2]. We give results of numerical experiments with parallel solution of both coercive and semicoercive problems to demonstrate numerically scalability of the algorithms presented that was predicted by the theory.

The research was carried out in collaboration with my colleagues V. Vondrák and D. Horák.

Scalable algorithm for solving 3D contact problems with friction. **Radek Kučera** (TU Ostrava, Czech Republic) IC/MT1926/026

The contribution deals with solving of contact problems with Coulomb friction for a system of 3D elastic bodies. First we introduce auxiliary problem with given friction defining a mapping Φ which associates with a given slip bound the normal contact stress in the equilibrium state. The solution to the contact problem with Coulomb friction is characterized by a fixed point of Φ and the method of successive approximations is used for its computation.

The finite element discretization of the contact problem with given friction leads to constrained minimization of a nonsmooth functional. After using the duality theory, the problem can be rewritten as minimization of a strictly convex quadratic functional with separable convex constraints. To compute the solution we can use a newly developed active-set based algorithm (QPC) that combines the conjugate gradient method with the gradient projections. This algorithm has the rate of convegence in terms of the spectral condition number of the Hessian matrix.

The FETI domain decomposition method impose, in addition, the linear equality constraints in the algebraic formulation of the problem. In order to satisfy them, the iterative augmented Lagrangian algorithm can be used, in which the outer loop updates the Lagrange multipliers for the equality constraints, while the inner loop is represented by the QPC algorithm. Moreover, the update rule for the penalty parameter is introduced that depends on the increase of the augmented Lagrangian.

The main goal is to extend theoretical results obtained recently for 2D contact problems. In particular, it can be proved that if the algorithm is applied to the class of problems with uniformly bounded spectrum of the Hessian matrix, then the algorithm finds an approximate solution at $O(1)$ matrix-vector multiplications.

IC/MP108/010: Interface methods and applications in multi-phase problems.

Organiser: Zhilin Li (North Carolina State University, USA)
Co-organiser: Xiaolin Li (SUNY at Stony Brook, USA)
Co-organiser: Kazufumi Ito (North Carolina State University, USA)

Many scientific and engineering problems require a detailed understanding of physics coupled across a dynamically moving interface separating multi-material or multiphase domains. This minisymposium focus on numerical methods in dealing with such problems. The presentations in this minisymposium will address the propagation of the interface geometry, the coupling across the interface of the interior physics on each side of the interface and the physics at the boundary defined by the moving interface.

Fast locally-corrected boundary-integral methods for elliptic systems. **John Strain** (University of California, Berkeley, USA) IC/MT1363/026

Classical potential theory converts linear constant-coefficient elliptic problems in complex domains into integral equations on interfaces, and generates robust, efficient numerical methods. The conversion is usually carried out for a particular situation such as the Poisson equation in dimension 2, and the efficiency of the resulting methods then depends on detailed analysis of the appropriate special functions.

We present a general conversion scheme which leads naturally to a fast general algorithm: arbitrary elliptic problems in arbitrary dimension are converted to first-order systems, a periodic fundamental solution is mollified for convergence, and the mollification is locally corrected via Ewald summation. Local linear algebra and the elementary theory of distributions yield a simple boundary integral equation. With the aid of a new nonequidistant fast Fourier transform for piecewise polynomial functions, the resulting numerical methods provide highly accurate solutions to general elliptic systems in complex domains.

The augmented immersed-interface method for Stokes and Navier–Stokes equations with interfaces/irregular domains. **Zhilin Li** (North Carolina State University, USA) IC/MT1812/026

The Immersed Interface Method (IIM) was motivated by the Peskin's Immersed Boundary Method. The IIM shares many characteristics of the IB method. Both methods use simple grid structure. The original motivation of IIM is to improve the accuracy of the IB method from first order to second order. This has been achieved by incorporating the jump conditions into numerical schemes near or on the interface. In this talk, I will focus on some recent work using IIM to solve incompressible Stokes and Navier Stokes equations with singular sources and discontinuous viscosity. One of techniques if the augmented approach in which fast Poisson solvers can be used. In the augmented approach, we introduce augmented variables so that the jump conditions for the velocity and the pressure can be decoupled, and the fast Poisson solvers can be employed even though the viscosity is discontinuous. We will also discuss this approach for flows on irregular domains. Numerical examples will also be presented.

An accurate Lagrange multiplier finite element method for interface problems. **Rachid Touzani** (Université Clermont-Ferrand, France), Gunther Peichl (Universität Graz, Austria) IC/MT1596/026

We consider the numerical solution of some elliptic interface problems. Such problems involve the same type of singularities that appear in interface and free boundary problems. For such problems, we design a new finite element method that avoid using fitted meshes. Using a hybrid technique localized at interface elements and a Lagrange multiplier, we construct a finite element that enjoys optimal convergence rates. Numerical experiments confirm the theoretical ones.

Simulating flow around solid body using immersed boundary method. **Lai Ming-Chih** (National Chiao Tung University, Taiwan) IC/MT1505/026

A new immersed boundary (IB) technique for the simulation of flow interacting with solid boundary is presented. The present formulation employs a mixture of Eulerian and Lagrangian variables, where the solid boundary is represented by discrete Lagrangian markers embedding in and exerting forces to the Eulerian fluid domain. The interactions between the Lagrangian markers and the fluid variables are linked by a simple discretized delta function. Based on the direct momentum forcing on the Eulerian grids, a new interpolating force formulation on the Lagrangian marker is proposed, which ensures the satisfaction of the no-slip boundary condition on the immersed boundary in the intermediate time step. This forcing procedure involves solving a banded linear system of equations whose unknowns consist of the boundary forces on the Lagrangian markers; thus, the order of the unknowns is one-dimensional lower than the fluid variables. Four different test problems have been compared with previous experimental and numerical results.

Multiphase flow theory of diffuse interfaces and transformation fronts. **Richard Saurel** (Université de Provence Aix-Marseille I, France) IC/MT1705/026

The numerical smearing of interfaces separating compressible fluids involves artificial mixing zones for which determination of the correct thermodynamic state is difficult.By considering such zones as physical multiphase mixtures reliable modelling is possible. The non-equilibrium multiphase flow model of Baer and Nunziato (1986) is considered. It is reduced to the single velocity and single pressure but multi-temperatures flow model of Kapila et al. (2001). This model is examined for the modelling of diffuse interfaces separating compressible fluids. This non-conservative hyperbolic model with five partial differential equations requires shock relations for its closure. The shock relations derived in Saurel et al. (2006a) are summarised. Then, extensions to extra physics are considered.

First, capillary effects at interfaces separating compressible fluids are introduced. A conservative formulation is obtained (Perigaud and Saurel (2005)). Second, heat and mass transfer at interfaces are introduced in order to deal with phase transition fronts (Saurel et al., 2006b). When the interface structure is numerically solved evaporation jump conditions are recovered. In particular, the kinetic CJ relation proposed by Simoes Moreira and Shepherd (1999) for evaporation fronts in metastable liquids is obtained as an eigenvalue of the limit system with stiff thermal and chemical relaxation. Examples for multidimensionnal cavitating flows are presented.

Compact fourth-order finite-difference schemes for elliptic systems and interface problems. **Kazufumi Ito** (North Carolina State University, USA) IC/MT2489/026

Compact fourth-order Cartesian grid-based finite-difference methods are developed for Stokes systems and elliptic interface problems. The resulting system has the $M-$matrix property and thus satisfies the discrete maximum principle. Our methods are based on the continuation of solution across the interface using multi-variable Taylor's expansion of the solution about selected interface points and a set of appropriate interface conditions. The interface conditions are derived from the continuity of the solution and its flux and equating the equation and its derivatives. The method is also successfully extended to the heat equation. The validity and effectiveness of the proposed methods are demonstrated through our numerical results

A coupled IIM–BEM numerical method for the simulation of cell motion in single-cell traps. **Boo Khoo** (National University of Singapore) IC/MT2059/026

We present a coupled Immersed Interface Method–Boundary Element Method (IIM-BEM) numerical technique that can study the (dynamic) behavior of target cells in detail, and describe the cell deformation and motion under the effects of both the electric and the (hydrodynamic) flow fields. We apply this technique to analyze the characteristics of a hybrid electrical-mechanical trap for single-cell trapping in the presence of a cavity on a channel wall. The Immersed Interface Method provides the means of calculating the hydrodynamic effects and influence of fluid-structure interaction such as cell movement and deformation next to the cavity wall, and the Boundary Element Method is used to calculate the electric fields and their effects on the particle. We report on the effect of different combinations of electrode positions and mechanical properties of the trap on the maximum loading and unloading Reynolds numbers, and further show the effect that cells moving with the flow have on cells which have been already trapped in the cavity.

EJStokes: an explicit jump correction to the fast fictitious-force 3D Stokes solver. **Andreas Wiegmann** (Fraunhofer ITWM, Kaiserslautern, Germany), Liping Cheng (Fraunhofer ITWM, Kaiserslautern, Germany) IC/MT2491/026

Wiegmann [1] described the fast fictitious-force 3D Stokes solver for solving steady Stokes equations of the flows in porous media and geometrically complex materials. It is efficient and fast but implements the boundary conditions in tangential directions a half mesh width away from the correct locations. That is because in a MAC grid, the solid interfaces fall between grid cells for the variables in tangential directions. The method enforces the no-slip boundary conditions a half mesh size inside the interfaces. To achieve higher accuracy, this paper adopts a jump correction scheme. The jump correction is derived by using Taylor expansions at the interface points. The expression of the discretized correction terms shows agreement with analytical formulation of a singular force represented on the surface in Stokes equations. With a fictitious force term in normal direction and a jump correction term in tangential directions expressed as unknown body forces, the fast Fourier solver can still be utilized by extending all variables in the solid voxels. The Schur-complement formulation shows the resulting matrix is not symmetric. However, the jump corrected method obtains more accurate results, which is demonstrated by the Poiseuille flow in a channel and in a circular pipe. The accuracy is also verified by comparing to known analytical/numerical solutions for the example of slow flow through a periodic array of spheres centered in a unit cell.

IC/MP59/026: Partial differential equations and Sobolev gradients.

Organiser: Robert Renka (University of North Texas, USA)
Co-organiser: John Neuberger (University of North Texas, USA)

The Sobolev gradient method is a gradient descent method designed to compute critical points of a discretization of a functional of the form $\phi(u) = \int_\Omega F(Du)$, where D is a differential operator, and u is an element of some Sobolev space for which $F(Du)$ is integrable. The Fr'echet derivative of ϕ at u is uniquely represented by an element of the Sobolev space, termed the Sobolev gradient. The central idea of the method is to use the discretized Sobolev gradient rather than the ordinary Euclidean gradient in a method such as steepest descent for minimizing a discretization of ϕ. The resulting method is one of preconditioned gradient descent with an effective preconditioner that arises in a very natural and elegant manner. While the primary application is numerical solution of nonlinear partial differential equations, the method has been extended to geometric modeling problems, inverse problems, optimal control problems, and image processing problems.

Sobolev gradients: superconductivity and other applications. **John Neuberger** (University of North Texas, USA) IC/MT1506/026

We indicate use of Sobolev gradients for Ginzburg–Landau functionals of superconductivity. We indicate how moats and holes in a superconducting medium energentically attract vortices. Other applicatons are indicated including one to problems in transonic flow. Some convergence results are given. A related result is a new Nash–Moser type inverse theorem.

Work on superconductivity is in collaboration with Robert Renka.

Gradient-flows and gradient-like flows. **Ralph Chill** (Universite Paul Verlaine Metz, France) IC/MT1929/026

The title of this talk could also be: *Gradient flows and gradient-like flows associated with a single energy functional.* We will in fact first review that given an energy functional such as the classical functional

$$E(u) := \tfrac{1}{2}\int_\Omega |\nabla u|^2 + \int_\Omega F(u)$$

defined on $H^1_0(\Omega)$ ($\Omega \subset \mathbb{R}^n$ open) it is possible and natural to associate *several* gradient flows and gradient-like flows, usually partial differential equations. It is remarkable that all these flows have similar asymptotic behaviour: for example, solutions of the various flows converge to an equilibrium point as soon as E satisfies a gradient inequality. We will discuss a similar program for energy functionals arising in geometric evolution equations and show how a gradient inequality can also be used to prove global existence.

Neuberger gradient method applied to design of martensitic microvalves. **Sultan Sial** (Lahore Inst. Of Management Sciences, Pakistan) IC/MT1355/026

Martensitic materials are of interest since all shape-memory materials are martensitic. The method of Neuberger gradients allows for the efficient optimization of free energy of Ginzburg-Landau type. In this talk the formulation and optimization of a functional related to the design of martensitic microvalves is considered.

Application of the Sobolev steepest descent to hyperbolic Monge–Ampere equations. **Tamani Howard** (University of North Texas, USA) IC/MT1349/026

We will address both numerical and theoretical applications of the Sobolev gradient steepest descent method to some hyperbolic Monge-Ampère equations. In the numerical case, we will disscuss the construction of the discrete Sobolev gradient and present some numerical solutions to the hyperbolic Monge-Ampère equation:

$$det(D^2\ z) = f$$

on [0, 1]2 in the two cases where $f = -1$ and $f = -(1 + z_x^2 + z_y^2)^2$. We will also explore the effect of some imposed boundary conditions on the solutions. Finally, in the theoretical case, we will prove convergence of the continuous Sobolev gradient steepest descent in the Sobolev space $H^{9,2}([0,1]^2)$ to show local existence of solutions to the hyperbolic Monge-Ampère equation $det(D^2\ z) = -1$.

Curve-fitting with a Sobolev gradient method. **Robert Renka** (University of North Texas, USA) IC/MT1044/026

Consider the problem of constructing a mathematical representation of a curve that satisfies constraints such as interpolation of specified points. This problem arises frequently in the context of both data fitting and Computer Aided Design. We treat the most general problem: the curve may or may not be constrained to lie in a plane; the constraints may involve specified points, tangent vectors, normal vectors, and/or curvature vectors, periodicity, or nonlinear inequalities representing shape-preservation criteria. Rather than the usual piecewise parametric polynomial (B-spline) or rational (NURB) formulation, we represent the curve by a discrete sequence of vertices along with first, second, and third derivative vectors at each vertex, where derivatives are with respect to arc length. This provides third-order geometric continuity and maximizes flexibility with an arbitrarily large number of degrees of freedom. The free parameters are chosen to minimize a fairness measure defined as a weighted sum of curve length, total curvature, and variation of curvature. We thus obtain a very challenging constrained optimization problem for which standard methods are ineffective. A Sobolev gradient method, however, will be shown to be particularly effective.

Image interpolation: a novel variational method. **Santiago Betelu** (University of North Texas, USA) IC/MT1176/026

We study a novel variational method for the interpolation of digital images. In this problem, an image has a region R where the data has been lost or corrupted, and one wants to interpolate this region by using the information from another region M where the image is intact. To formulate the problem, we define a function $u(x, y)$ representing the luminance values of the image, and define an energy E as the integral of a functional $F(u)$ calculated over R. The functional F is estimated from the data in M using probabilistic arguments. The solution of the problem is reduced to a gradient descent minimization of the energy E. Numerous examples are shown and the advantages and disadvantages of the method are discussed.

Uniqueness and reconstruction for the inverse conductivity problem. **Ian Knowles** (University of Alabama, USA) IC/MT2024/026

The inverse conductivity problem centers around the determination of the conductivity p in the conductivity equation $\nabla \cdot (p(x)\nabla u) = 0$ in a region Ω, of dimension two or greater, from a knowledge of the Dirichlet-Neumann mapping Λ_p on the boundary of Ω. We discuss a new method for proving that Λ_p uniquely determines p when p is Lipschitz continuous, as well as steepest descent methods for computing p from Λ_p.

Inverse problems for Maxwell systems. **Malcolm Brown** (Cardiff University, UK), Mohamad Zahran (Hariri Canadian University, Lebanon) IC/MT3667/026

We shall show that the coefficients in the Maxwell system may be recovered from partial boundary data. Theoretical results will be illustrated with numerical examples.

IC/MP265/026: Efficient methods for Hamilton–Jacobi equations.

Organiser: Alexander Vladimirsky (Cornell University, USA)
Co-organiser: James Sethian (University of California, Berkeley, USA)
Co-organiser: Ian Mitchell (University of British Columbia, Canada)

Hamilton–Jacobi equations have natural interpretations in deterministic and stochastic optimal control, differential games, and anisotropic front propagation. Efficient methods for solving these PDEs make useful tools for practitioners in robotics, optimal control, seismology, geophysics, image processing, material science, and financial engineering.

A number of fast schemes were recently introduced for different sub-classes of Hamilton–Jacobi PDEs. The proposed methods reflect a variety of approaches and perspectives (semi-Lagrangian and Eulerian; based on viscosity solutions and on viability kernels; mirroring the properties of label-setting and label-correcting algorithms in the discrete dynamic programming; based on paraxial approximations or on alternating-direction Gauss–Seidel relaxation). This mini-symposium will focus on comparing the efficiency and limitations of these techniques as well as on applicability to other equations and application areas.

Discrete network flows and continuous PDEs: new applications and new Dijkstra-like methods. **James Sethian** (University of California, Berkeley, USA) IC/MT3059/026

Fast Marching Methods are part of a class of Dijkstra-like methods for solving the Eikonal equation. Using this as a starting point, the author will discuss some applications that straddle the boundary between discrete network flow problems and continuous Hamilton-Jacobi equations. Numerous new applications will be presented, including optimal solutions of geodesics on complex terrain.

Fast sweeping methods for convex Hamilton–Jacobi equations. **Hongkai Zhao** (University of California, Irvine, USA) IC/MT1629/026

I will first give a general review for the fast sweeping method, the algorithm, convergence, error estimate and optimal complexity for Eikonal equations. Then I will talk about our recent work (joint work with J. Qian and Y. Zhang) on fast sweeping method for general convex Hamilton-Jacobi equations on unstructured mesh. Finally I will show applications of fast sweeping strategy to other hyperbolic or hyperbolic dominant problems.

Wide-stencil schemes for second-order degenerate elliptic PDEs. **Adam Oberman** (Simon Fraser University, Canada) IC/MT1092/026

The theory of viscosity solutions gives powerful existence, uniqueness and stability results for first- and second-order degenerate elliptic partial differential equations. The approximation theory developed by Barles and Sougandis in the early nineties gave conditions for the convergence of numerical schemes.

While there has been a lot of work on first-order equations, there has been very little work on genuinely nonlinear or degenerate second-order equations. This despite the fact that many of these equations are of the subject of current research and applications. For example: level-set motion by mean curvature, the Infinity Laplacian, the PDE for the value function in Stochastic Control, the Monge–Ampère equation.

In this talk, we build convergent schemes for the aforementioned equations, and also for some less well-known or newer equations, including the Pucci Equations and a new PDE for the convex envelope. We will also discuss a general framework for building these types of schemes. The majority of the work discussed can be found on the author's webpage.

Approximation of solutions to Burger's, Lighthil–Whitham–Richards' and Moskowitz HJB equation. **Patrick Saint-Pierre** (Université Paris Dauphine, France) IC/MT1114/026

c

IC/MP265/026: Efficient methods for Hamilton–Jacobi equations. #2

Ordered upwind methods for Hamilton–Jacobi PDEs. **Alexander Vladimirsky** (Cornell University, USA) IC/MT2991/026

In discrete-state-space optimal control problems (e.g., shortest-path problems on graphs), the dynamic programming approach yields a large coupled system of non-linear equations. To solve this system efficiently, label-setting algorithms (e.g., Dijkstra's and Dial's methods) re-order the computations and provide an upper bound K on the number of times a single equation has to be solved. The efficiency stems from the fact that K is independent of the total number of equations and of the costs/penalties assigned to the edges of the graph.

Ordered Upwind Methods (OUMs) exploit similar ideas to solve systems arising from causal discretizations of static Hamilton–Jacobi PDEs. We will describe a method for producing causal discretizations, comparing the different effects of Hamiltonian non-convexity, anisotropy and inhomogeneity on the method's accuracy and computational complexity. We will illustrate our method with several examples from optimal control, differential games, and front propagation.

Fast marching and semi-Lagrangian schemes for convex and non-convex Hamilton–Jacobi equations. **Maurizio Falcone** (Universita' di Roma "La Sapienza", Italy) IC/MT2506/026

The talk presents recent results on the approximation of convex and non convex Hamilton-Jacobi equations via semi-Lagrangian approximation schemes. We will examine a Fast Marching semi-Lagrangian approximation for eikonal type equations as well as efficient approximation schemes for non convex Hamiltonians. Several applications to control and game problems, optimal path finding and image processing will be presented.

Works in collaboration with E. Cristiani.

An efficient algorithm to solve perturbed shortest path problems. **Lars Grüne** (Universität Bayreuth, Germany), Oliver Junge (TU München, Germany), Marcus von Lossow (Universität Bayreuth, Germany) IC/MT1541/026

Perturbed shortest path problems form a class of discrete time dynamic games which arise, for instance, from the semi-discretization of Hamilton–Jacobi–Isaacs equations related to pursuit–evasion games or robust stabilization problems. In this talk we present an algorithm for the solution of such problems on a finite state space, along with a set oriented discretization technique which allows to approximate a problem on a continuous state space by problems on finite spaces.

Unlike most efficient computational methods for optimal control problems, which are not easily adapted to the dynamic game setting, here we will show that one of the fastest known methods for shortest path problems, Dijkstra's algorithm, can be extended to a "min–max Dijkstra" algorithm with only moderate increase in the computational complexity. We will discuss the basic idea of this extension as well as implementational aspects. Furthermore we show how a judicious interplay between the set oriented discretization and the min–max Dijkstra algorithm can be used in order to compute upper and lower approximations to the game's value function, a feature particularly useful for suboptimal feedback synthesis.

The proposed method will be illustrated by a number of numerical examples.

Theoretical and experimental results on the complexity of schemes for anisotropic Hamilton–Jacobi equations. **Ian Mitchell** (University of British Columbia, Canada) IC/MT1639/026

The stationary (or static or time-independent) Hamilton-Jacobi equation arises in optimal path planning through continuous domains. In this talk we examine the anisotropic case, where the cost to traverse the path may depend on the direction of travel as well as the states visited. Both iterative and non-iterative schemes are considered, and some conclusions are drawn about the types of grids and cost functions for which various schemes are more or less effective.

IC/MP203/026: Least-squares finite-element methods for partial differential equations.

Organiser: Chad Westphal (Wabash College, USA)

The least-squares approach to numerically approximating the solution to partial differential equations (PDEs) is a powerful methodology that offers several distinctive features not present in more traditional methods. In its simplest form, a least-squares norm minimization principle is applied to the residual of an appropriate first-order system of PDEs, resulting in a symmetric variational problem which is discretized in a finite element context. This allows complete flexibility in choosing finite element spaces for the unknowns, provides a reliable error estimator and leads to naturally positive definite linear algebraic systems that can often be solved with optimal complexity by multilevel iterative solvers.
This approach combines many ideas from the optimization and numerical PDE communities to solve difficult problems. The least-squares methodology puts significant emphasis on development of the original PDE system rather than the discretization or solver. Thus, in general, the key to success lies in choosing the right first-order system and norm in which to minimize over. Often, but not always, this formulation involves introducing new unknowns and additional, but consistent, equations to the system.
In recent years researchers have made great progress toward developing robust solution strategies for a growing number of applications. This minisymposium promises to highlight several challenging nonlinear problems in solid and fluid mechanics which have only recently been analyzed in a least-squares framework. Also of significance in this session are computational advances in h and p refinement techniques and treatment of problems with significant nonlinearities and singularities.

A least-squares finite-element method for visco-elastic fluid flow. **Chad Westphal** (Wabash College, USA) IC/MT1322/026

Viscoelastic materials are those with properties of both viscous fluids and elastic solids. With applications ranging from biological fluids to liquid crystal flows, these models are of general interest to many fields. While much progress has been made in recent years toward the accurate and efficient computational solution of equations for viscoelastic fluids, many difficultes persist. In this talk we present a least-squares finite element method for the steady Oldroyd type viscoelastic fluids. The least-squares methodology offers many attractive benefits which are particularly advantageous for this system. A weighted-norm approach is used to remove effects of corner singularities and a nonlinear nested iteration is used to reduce the overall computational work as well as to ensure good initial guesses for the nonlinear iteration. We also establish equivalence of the homogenous least-squares functional to a meaningful norm, ensuring well posedness of the numerical method in a small parameter regime. Numerical results are given for benchmark problems and large scale flow features are compared with well-known results.

Adaptive local-refinement strategy for FOSLS finite-element method. **Joshua Nolting** (University of Colorado at Boulder, USA) IC/MT1624/026

Adaptive local refinement enables us to concentrate computational resources in areas that need special attention, for example, near steep gradients and singularities. The Least-Squares Finite Element method FOSLS (First Order System Least Squares), yields a very sharp *a posteriori* error measure for each element. This is a benefit that is very important for adaptive refinement strategies, because determining what elements need to be refined, often relies on the measured error for each element. This talk will discuss a strategy for determining which elements to refine in order to optimize the accuracy/computational cost. Set in the context of a full multigrid algorithm, our strategy leads to a refinement pattern with nearly equal error on each element. Further refinement is essentially uniform, which allows for an efficient parallel implementation. Numerical experiments will be presented.

First-order-system least-squares for elasto-plasticity. **Gerhard Starke** (Universität Hannover, Germany) IC/MT1903/026

A least-squares mixed finite element method for the incremental formulation of elasto-plasticity using a plastic flow rule of von Mises type with isotropic hardening is presented. This approach is based on the use of the stress tensor, in addition to the displacement field, as independent process variables. The nonlinear least-squares functional is shown to constitute an *a posteriori* error estimator on which an adaptive refinement strategy may be based. For the finite element implementation under plane strain conditions, quadratic (i.e., next-to-lowest order) Raviart-Thomas elements are used for the stress approximation while the displacement is represented by standard quadratic conforming elements. The method constitutes an extension of a least-squares mixed finite element approach for linear elasticity recently studied in joint work with Zhiqiang Cai and Johannes Korsawe.
Our main theoretical result is that, under the assumption of a plastic flow rule of von Mises type with isotropic hardening, the nonlinear least-squares functional associated with elasto-plasticity is elliptic with respect to an appropriate product space for the stresses and displacements.

Computational results for a benchmark problem of elasto-plasticity under plane strain conditions are presented in order to illustrate the effectiveness of the least-squares approach. Our computational results also suggest that the approximation properties actually deteriorate in the perfectly plastic case. Despite this deterioration of the approximation order in the perfectly plastic case, the adaptive implementation of the least-squares finite element method provides remarkably accurate results, in particular for the stresses.

First-order system least-squares methods for the Signorini contact problem in linear elasticity. **Frank Attia** (Universität Hannover, Germany), Gerhard Starke (Universität Hannover, Germany) IC/MT2687/026

A first-order system least squares formulation for the Signorini problem modelling frictionless contact in linear elasticity is studied. The displacement field and the stress tensor are used as independent process variables. To treat the boundary conditions, appropriate boundary functionals are part of the least squares functional. Coercivity and continuity of this functional allow to use the functional as an *a posteriori* error estimator, which will be used as a basis for an adaptive refinement strategy. For the displacement field, conforming quadratic elements (P2) or non-conforming Mardal-Tai-Winther elements (MTW) can be used. Note that the MTW elements lead to uniform approximation properties for nearly incompressible materials. Computational results for a test problem of Hertzian contact will be shown.

IC/MP258/026: Advances in discontinuous Galerkin methods.

Organiser: Thomas Wihler (McGill University, Canada)
Co-organiser: Ilaria Perugia (Università degli Studi di Pavia, Italy)

Discontinuous Galerkin (DG) finite element methods have gained considerable interest in recent years. The remarkable research activity in this area results, amongst other reasons, from a number of interesting features of DG schemes, which are appealing from both an analytical and computational view point. The goal of this minisymposium is to focus on: new results for DG discretizations in solid and fluid mechanics, and electromagnetics; error analysis; *a posteriori* error estimation and adaptivity; time-dependent problems; high-order DG methods; nonlinear PDE.

Adaptive DG methods for the Stokes problem. **Ohannes Karakashian** (University of Tennessee, USA) IC/MT3507/026

We present some recent results on DG methods for the Stokes problem including lower and upper *a posteriori* error bounds in the energy norm and convergence results for adaptive schemes based on the *a posteriori* bounds.

Hybridized globally divergence-free LDG methods for the Stokes problem. **Dominik Schötzau** (University of British Columbia, Canada) IC/MT2764/026

We devise and analyze a new local discontinuous Galerkin (LDG) method for the Stokes equations of incompressible fluid flow. This optimally convergent method is obtained by using an LDG method to discretize a vorticity-velocity formulation of the Stokes equations and by applying a new hybridization to the resulting discretization. One of the main features of the hybridized method is that it provides a globally divergence-free approximate velocity without having to construct globally divergence-free finite dimensional spaces; only element-wise divergence-free basis functions are used. Another important feature is that it has significantly less degrees of freedom than all other LDG methods in the current literature; in particular, the approximation to the pressure is only defined on the faces of the elements. On the other hand, we show that, as expected, the condition number of the Schur-complement matrix for this approximate pressure is of order h^{-2} in the mesh size h. Finally, we present numerical experiments that confirm the sharpness of our theoretical *a priori* error estimates.

Discontinuous Galerkin methods for anisotropic and possibly locally nondefinite diffusion with advection. **Alexandre Ern** (École Nationale des Ponts et Chaussées, France), Daniele Antonio Di Pietro (École Nationale des Ponts et Chaussées, France), Jean-Luc Guermond (Texas A&M University, USA) IC/MT1297/026

In the present work we construct and analyze a Discontinuous Galerkin method to solve advection-diffusion PDEs with anisotropic and possibly locally nondefinite diffusion. The method is designed so as to automatically detect the so-called elliptic-hyperbolic interface without requiring any further intervention. The key to the method is the use of weighted average and jump operators. The error analysis provides optimal estimates in the broken graph norm and is consistent with well-known results when the problem is either hyperbolic or uniformly elliptic. The theoretical results are supported by numerical evidence.

hp-adaptive discontinuous Galerkin methods for the shallow-water equations. **Clint Dawson** (University of Texas at Austin, USA), Ethan Kubatko (University of Texas at Austin, USA), Joannes Westerink (University of Notre Dame, USA) IC/MT3823/026

The shallow water equations model highly nonlinear hydrodynamic phenomena. The hydrodynamics are driven by tide, winds and waves, gravity, Coriolis and other forces. Typical domains include deeper waters transitioning to continental shelves and shallow coastal regions. Solutions to these models exhibit complex, multiscale spatial and temporal behavior. Dynamically adaptive finite element methods including discontinuous Galerkin methods are currently being pursued for these models. DG methods are of particular interest, because of their ability to handle local h- and p-adaptivity, local mass conservation, and ability to model both smooth and rough flow. In this talk, we will discuss recent advances in the development and analysis of DG methods for the shallow water equations, with applications to flows in inlets, estuaries, and storm surges along the Gulf Coast of the U.S.

Discontinuous Galerkin finite-element approximation of nonlinear elastic waves. **Endre Süli** (University of Oxford, UK) IC/MT1617/026

We survey recent developments concerned with the construction and convergence analysis of discontinuous Galerkin finite element methods for second-order systems of nonlinear hyperbolic equations of the form

$$\partial_t^2 u_i - \sum_{\alpha=1}^{d} \partial_{x_\alpha} S_{i\alpha}(\nabla u(t,x)) = f_i(t,x), \qquad i = 1,\dots,d,$$

with $\partial_{x_\alpha} = \partial/\partial x_\alpha$, in a bounded spatial domain $\Omega \subset \mathbb{R}^d$, subject to mixed Dirichlet–Neumann boundary conditions. Evolution problems of this kind arise as mathematical models in nonlinear elastic wave propagation.

We first discuss the case when the Piola–Kirchhoff stress tensor $S = (S_{i\alpha})$ is uniformly monotone on $\mathbb{R}^{d\times d}$; the energy functional

$$J : v \mapsto J(v) := \int_\Omega W(\nabla v(x))\,\mathrm{d}x - \int_\Omega f(x)\cdot v(x)\,\mathrm{d}x - \int_{\Gamma_N} g_N(s)\cdot v(s)\,\mathrm{d}s,$$

(where W is the stored energy density function related to S via $S = \nabla W$, $\Gamma_N \subset \partial\Omega$ is the Neumann part of the boundary and g_N is the Neumann boundary datum,) associated with the corresponding static problem

$$-\sum_{\alpha=1}^{d} \partial_{x_\alpha} S_{i\alpha}(\nabla u(x)) = f_i(x), \qquad i = 1,\dots,d,$$

is then convex. Granted sufficient smoothness of u, we show that the discontinuous Galerkin method exhibits an optimal rate of convergence with respect to the spatial discretization parameter.

Using a broken Gårding inequality we extend our convergence results to the case when we only require that the fourth-order elasticity tensor $A = \nabla S$ satisfies a Legendre–Hadamard condition. The associated stored energy density function W is then only rank-1 convex.

The talk is based on joint work with Christoph Ortner (University of Oxford).

Discontinuous Galerkin methods using solutions of the PDE. **Peter Monk** (University of Delaware, USA) IC/MT3588/026

We shall show that a general class of symmetric hyperbolic systems can be discretized using an upwind discontinuous Galerkin method using solutions of the underlying partial differential equation as basis functions for the approximation. With an appropriate choice of degrees of freedom this gives rise to the Ultra Weak Variational Formulation due to Cessenat and Despres.

We shall illustrate this approach with an application to Maxwell's equations, and to the Helmholtz equation. The method is most useful at higher frequencies than is usual for finite element methods, and for moderate accuracy (the conditioning of the system prevents very high accuracy).

We shall present the current state of error analysis of the method using the Helmholtz equation as model problem.

This paper presents joint work with Tomi Huttunen and Matti Malinen from the Department of Applied Physics at the University of Kuopio, Finland.

Multigrid algorithms for some new interior-penalty methods. **Susanne Brenner** (Louisiana State University, USA) IC/MT3485/026

We will discuss multigrid algorithms for some new interior penalty methods. Both convergence analysis and numerical results will be presented.

Discontinuos Galerkin approximation for advection–diffusion–reaction problems. **Blanca Ayuso** (Departamento de Matematicas, Universidad Autonoma, Spain), L. Donatella Marini (Università degli Studi di Pavia, Italy) IC/MT5066/026

In this talk, following the weighted-residual approach recently introduced by Brezzi *et al.* for elliptic problems, we discuss the design of DG approximations for advection–diffusion–reaction problems. We devise the basic ingredients to ensure stability and optimal error estimates in suitable norms, and propose two new methods.

The talk is based on joint work with L. Donatella Marini from the University of Pavia.

IC/MP239/027: Recent advances in algebraic multigrid with applications.

Organiser: Michael Gee (TU München, Germany)
Co-organiser: Marzio Sala (ETH Zürich, Switzerland)

The minisymposium focuses on recent advances in algebraic multigrid methods (AMG) and application of multigrid methods to complex, parallel and large scale applications. While such methods are widely used and accepted for standard applications such as elliptic partial differntial equations, formulation and application of AMG methods to more complex applications such as e.g. multiphysics, fluid dynamics, nonconforming discretizations, anisotropy or Maxwell equations is a very active field of research. The minisymposium provides an overview of current state of the art algebraic multigrid formulations, recent developements and challenging applications. Topics of interest include (but are not restricted to) algebraic multigrid in the context of the following:

- nonlinear multigrid;
- fluid dynamics and multiphysics applications;
- nonsymmetric problems;
- Maxwell equations;
- nonconforming discretizations, constraints and saddle problems;
- adaptive multigrid techniques;
- anisotropic problems and automatic anisotropy detection;
- formulations;
- implementation issues and software engineering;
- scalability;
- algebraic multigrid for matrix-free problems.

Performance of AMG-based preconditioners for fully-coupled Newton–Krylov solution of transport/reaction systems. **John Shadid** (Sandia National Laboratories, USA) IC/MT2572/027

A current challenge before the computational science and numerical mathematics community is the efficient computational solution of multi-physics systems. These systems are strongly coupled, highly nonlinear and characterized by multiple physical phenomena that span a very large range of length and time scales. The myriad of complex, interacting physical mechanisms can balance to produce steady-state behavior, nearly balance to evolve a solution on a dynamical time scale that is long relative to the component time-scales, or they can be systems that are dominated by one (or a few) process(es). These characteristics make the computational solution of these system extremely challenging.

In this presentation I will briefly motivate the need for fully-coupled Newton-based solution techniques for coupled nonlinear multiple-time-scale PDE systems. The resulting large sparse linear systems that are generated by these methods are solved by the application of parallel preconditioned Krylov methods. The preconditioners we consider include additive Schwarz domain decomposition (DD) and multi-level preconditioners. The multi-level preconditioners are based on geometric and algebraic methods as well as approximate block factorization techniques.

To demonstrate the capability of these methods I will present performance results for representative transport/reaction systems such as chemically reacting flows, semiconductor devices and possibly some recent plasma system simulations. In this context I will discuss robustness, efficiency, and the parallel and algorithmic scaling of solution methods.

This work was partially funded by the Department of Energy's Mathematical, Information and Computational Sciences Division, and was carried out at Sandia National Laboratories operated for the U.S. Department of Energy under contract no. DE-ACO4-94AL85000.

Point-based AMG for strongly-coupled PDE systems: recent developments for several industrial applications. **Tanja Clees** (Fraunhofer SCAI, Germany), Peter Thum (Fraunhofer Institute SCAI, Germany), Klaus Stüben (Fraunhofer SCAI, Germany) IC/MT2636/027

Algebraic multigrid (AMG) methods are known to be very efficient and robust solvers or preconditioners for large classes of problems, such as discretized scalar elliptic partial differential equations (PDEs). They can handle millions of variables and are especially suited for unstructured grids. Straightforward extensions of AMG, for example, so-called unknown-based (or function-based) approaches, have successfully been applied to different types of PDE systems. But for other important problems, the usage of more sophisticated methods, for example, so-called point-based approaches, is necessary.

Within the solver library SAMG, developed at Fraunhofer SCAI, a whole framework of point-based approaches has already been realized. The robustness and efficiency of concrete approaches for several practically important classes of applications, for instance, in semiconductor simulation (including strongly coupled drift-diffusion systems), has already been demonstrated.

For some other important application classes, efficient and robust (S)AMG strategies have lately been developed. This includes PDE systems arising in oil reservoir simulation (strongly coupled black oil as well as compositional models; geophysics). For others, promising strategies have recently been designed. Among such application classes are computational fluid dynamics (Navier-Stokes equations) and simulations of electrochemical machining and plating processes (PDE systems containing of one or more of the following building blocks: diffusion, convection, migration, reaction terms, network equations).

In this talk, we discuss progresses made for such PDE systems. The focus will be on approaches which have recently been or can easily be integrated into industrial simulation codes. In particular, we propose a new, automatic and adaptive solver and parameter switching strategy. Among important components are robust point-based AMG approaches with ILUT smoothing as well as an automatic ILUT-parameter switching strategy. We will present recent results for applications in industrial oil reservoir simulation and discuss promising extensions for other application classes.

High-performance parallel multigrid for large-scale shock physics simulations. **Jonathan Hu** (Sandia National Laboratories, USA) IC/MT3089/027

Parallel multigrid for large-scale shock physics simulations presents unique challenges, due to the need to simultaneously address parallel and algorithmic performance. System resources are often constrained because of demands from other parts of the application, coarse-level problems can have large communication to computation ratios, and load-balancing of the linear systems may be optimized for something other than the linear solver. We discuss our approaches to these challenges, and present numerical results on thousands of processors.

Smoothed agglomeration multigrid for incompressible flows. **Aleš Janka** (Université de Fribourg, Switzerland) IC/MT3164/027

We discuss advantages of using algebraic multigrid based on smoothed agglomeration for solving indefinite linear problems. The ingredients of smoothed agglomeration are used to construct a black-box monolithic multigrid method with idefinite coarse problems. Several techniques enforcing inf-sup stability conditions on coarse levels are presented. Numerical experiments are designed to support recent stability results for coupled algebraic multigrid. Comparison of the proposed multigrid preconditioner with other methods shows its robust behaviour even for very elongated geometries, where the pressure mass matrix is no longer a good preconditioner for the pressure Schur complement.

Long-range interpolation for parallel algebraic multigrid. **Ulrike Yang** (Lawrence Livermore National Laboratory, USA) IC/MT1323/027

Algebraic multigrid (AMG) is one of the most efficient and scalable parallel algorithms for solving sparse unstructured linear systems. However, for large three-dimensional problems, the coarse grids that are normally used in AMG often lead to growing complexity in terms of memory use and execution time per AMG V-cycle. Sparser coarse grids, such as the grids obtained by Parallel Modified Independent Set (PMIS) coarsening, compatible relaxation or aggressive coarsening remedy this complexity growth, but lead to non-scalable AMG convergence factors when traditional interpolation methods are used that include only distance-one coarse grid points in the interpolatory set. Since the coarse grid points are now located further apart and no longer meet criteria enforced in classical coarsening schemes, long range interpolation operators are needed.

In this paper we study the scalability of AMG methods that use sparser coarse grids, combined with long-range interpolation methods. AMG performance and scalability is compared for a variety of relevant test problems on parallel computers. It is shown that the increased interpolation accuracy largely restores the scalability of AMG convergence factors for PMIS-coarsened grids, without significantly affecting memory and execution time complexity per AMG V-cycle. This leads to a class of parallel AMG methods that enjoy excellent scalability properties on large parallel computers.

Maxwell's equations: discrete reformulation and algebraic multigrid solution. **Raymond Tuminaro** (Sandia National Laboratories, USA) IC/MT1584/027

We consider the linear solution of the eddy current equations. The large null space of the curl-curl operator within the eddy current equations complicates the application of most standard preconditioning techniques. Current solvers are often specialized techniques that cannot effectively leverage standard algebraic multigrid (AMG) methods and software for Laplace-type problems. We propose a new completely algebraic reformulation of the discrete eddy current equations along with a new AMG algorithm for this reformulated problem. The reformulation process takes advantage of a discrete Hodge decomposition to replace the discrete eddy current equations by an equivalent block 2x2 linear system whose diagonal blocks are discrete Hodge Laplace operators acting on edges and nodes, respectively. While this new AMG technique requires some special treatment in generating a grid transfer from the fine mesh, the coarser meshes can be handled using standard methods for Laplace-type problems. Our new AMG method is applicable to a wide range of compatible methods on structured and unstructured grids, including edge finite elements, mimetic finite differences, co-volume methods and Yee-like schemes. We illustrate the new technique, using edge elements in the context of smoothed aggregation AMG, and present computational results for problems in both two and three dimensions.

A multilevel method for discontinuous Galerkin finite-element equations: 3D anisotropic problems. **Johannes Kraus** (RICAM Linz, Austria), Satyendra Tomar (RICAM Linz, Austria) IC/MT3497/027

We construct optimal order multilevel preconditioners for certain discontinuous Galerkin (DG) finite element discretizations of three-dimensional (3D) anisotropic elliptic boundary-value problems. The presented approach has been introduced in an earlier work by the authors where the focus has been on 2D isotropic problems [1]. In this talk the analysis is extended, covering now 3D problems and incorporating the case of anisotropy. A specific assembling process is proposed which allows us to characterize the hierarchical splitting locally. This is also the key for a local analysis of the angle between the resulting subspaces. Applying the corresponding two-level basis transformation recursively, a sequence of algebraic problems is generated. It turns out that these discrete problems can be associated with coarse versions of DG approximations (of the solution to the original variational problem) on a hierarchy of geometrically nested meshes. New bounds for the constant γ in the strengthened Cauchy-Bunyakowski-Schwarz inequality are derived. The presented numerical results support the theoretical analysis and demonstrate the potential of this approach.

[1] J.K. Kraus and S.K.. Tomar: Multilevel preconditioning of elliptic problems discretized by a class of discontinuous Galerkin methods (submitted to SIAM J. Sci. Comput.)

A new smoothed aggregation multigrid method for anisotropic problems. **Michael Gee** (TU München, Germany), Raymond Tuminaro (Sandia National Laboratories, USA), Jonathan Hu (Sandia National Laboratories, USA) IC/MT2875/027

A new prolongator is proposed for smoothed aggregation multigrid. The proposed prolongator addresses a limitation of standard smoothed aggregation when it is applied to anisotropic problems. For anisotropic problems, it is fairly standard to generate small aggregates (used to mimic semi-coarsening) in order to only coarsen in directions of strong coupling. While beneficial to convergence, this can lead to a prohibitively large number of nonzeros in the standard smoothed aggregation prolongator and the corresponding coarse discretization operator. To avoid this, the new prolongator modifies the standard prolongator by shifting support (nonzeros within a prolongator column) from one aggregate to another to satisfy a specified nonzero pattern. This leads to a sparser operator which can be used effectively within a multigrid V-cycle. The key to this algorithm is that it preserves certain null space interpolation properties that are central to smoothed aggregation for both scalar and systems of PDEs. We present 2D and 3D numerical experiments that demonstrate that the new method is competitive with standard smoothed aggregation for scalar problems, and significantly better for problems arising from PDE systems.

IC/MP408/027: Adaptive and multilevel methods in electromagnetics.

Organiser: Ralf Hiptmair (ETH Zürich, Switzerland)
Co-organiser: Jinchao Xu (Pennsylvania State University, USA)

The finite-element or boundary-element discretization of quite a few variational problems arising in computational electromagnetics employs edge elements. As in other areas where finite elements are applied efficiency entails the use of fast multilevel iterative solvers and the adaptive choice of Galerkin trial spaces.

Talks in this minisymposium will provide a comprehensive survey of recent theoretical and algorithmic advances in the field of adaptive and multilevel methods in computational electromagnetics.

Local multigrids in electromagnetics. **Oliver Sterz** (Computer Simulation Technology, Germany) IC/MT1913/027

The efficient computation of electromagnetic problems requires adaptive methods in combination with fast iterative solvers like multigrid methods. In order to achieve potential optimality, standard implementations of multigrid schemes need a geometrical growth of the number of unknowns from one refinement level to the next. For adaptive computations this condition may be violated.

The concept of local multigrids can resolve the problem. This contribution provides an overview of the key aspects of an adaptive local multigrid scheme for electromagnetics including algorithmic details.

Local multigrid method in $H(\mathrm{curl})$. **Weiying Zheng** (Chinese Academy of Sciences), Ralf Hiptmair (ETH Zürich, Switzerland) IC/MT1341/027

We consider $\mathbf{H}(\mathbf{curl},\Omega)$-elliptic variational problems on bounded Lipschitz polyhedra and their finite element Galerkin discretization by means of lowest order edge elements. If the underlying mesh has been created by successive local mesh refinement, the so-called local multigrid correction scheme with hybrid smoothing provides a fast iterative solver for the resulting sparse linear system of equations. We review the convergence theory developed for local multigrid in a $H^1(\Omega)$-context and use it along with regular Helmholtz-type decompositions in order to establish asymptotic optimality of local multigrid for edge elements.

Auxiliary space preconditioners for electromagnetics. **Ralf Hiptmair** (ETH Zürich, Switzerland) IC/MT4840/027

We propose a general approach to preconditioning discrete $H(\mathbf{curl},\Omega)$-elliptic systems based on Poisson solvers. We prove mesh-independent effectiveness the preconditioners by appealing to the abstract theory of auxiliary space preconditioning. The main tool are discrete analogues of so-called regular decomposition results in the function space $H(\mathbf{curl},\Omega)$.

An important application of this general approach is the design of asymptotically efficient algebraic multigrid methods for the $H(\mathbf{curl})$-elliptic systems, based on algebraic multigrid methods for the discretized Poisson equation.

Parallel auxiliary space AMG for Maxwell problems. **Tzanio Kolev** (Lawrence Livermore National Laboratory, USA) IC/MT1317/027

Recently we implemented a parallel algebraic solver for definite Maxwell problems [1] based on the new Nedelec space decomposition by Hiptmair and Xu [2]. In this talk we are going to give an overview of the solver, and its numerical performance on large model electromagnetic problems. We will also consider several related methods, as well as extensions to more difficult problems.

IC/MP408/027: Adaptive and multilevel methods in electromagnetics. #2

Organiser: Ralf Hiptmair (ETH Zürich, Switzerland)
Co-organiser: Jinchao Xu (Pennsylvania State University, USA)

(For abstract, see session #1 above.)

hp-adaptive finite-element methods for Maxwell's equations: an update. **Leszek Demkowicz** (University of Texas at Austin, USA) IC/MT4880/027

I will report on our current work directed at working out a fully-automatic hp-adaptive finite element methodology for solving 3D time-harmonic Maxwell equations. The presentation will include:

- a summary of a current theoretical work related to the subject, including a recent result on polynomial extensions for H^1, $H(\mathrm{curl})$, and $H(\mathrm{div})$-conforming spaces defined on a cube,
- a discussion of an implementation for PML and its use in 3D simulations,
- 3D numerical examples.

The results represent a joint work with many colleagues including J. Kurtz, M. Costabel and M. Dauge.

Uniform a posteriori *error estimation for the heterogeneous Maxwell equations.* **Serge Nicaise** (Université de Valenciennes, France) IC/MT3328/027

We consider different *a posteriori* error estimators for the heterogeneous Maxwell equations with discontinuous coefficients in a bounded two or three dimensional domains. The continuous problem is approximated using conforming approximated spaces. The main goal is to express the dependence of the constants in the lower and upper bounds with respect to chosen norm and to the variation of the coefficients. For that purpose, some new interpolants of Clément/Nédélec type are introduced and some interpolation error estimates are proved. Some appropriate Helmholtz decompositions are also requested. Some numerical tests will be presented which confirm our theoretical results.

Equilibrated residual-error estimators for Maxwell equations. **Joachim Schöberl** (RWTH Aachen, Germany) IC/MT3173/027

A posteriori error estimates without generic constants can be obtained by a comparison of the finite element solution with a feasible function for a dual problem. A cheap computation of such functions via equilibration is well-known for scalar equations of second order. We simplify and modify the equilibration such that it can be applied to Maxwell's equations and edge elements. The two key ingredients are exact sequences for distributional finite elements, and a divergence free local decomposition of the residual. Numerical results for eddy current problems are presented.

RICAM Report 2006-19 is available from http://www.ricam.oeaw.ac.at/publications

Convergence analysis of adaptive edge-element approximations of the 3D eddy-current equations. **Ronald Hoppe** (Universität Augsburg, Germany) IC/MT2882/027

We consider Adaptive Edge Finite Element Methods (AEFEM) for the 3D eddy currents equations with variable coefficients based on the lowest order edge elements of Nédélec's first family with respect to an adaptively generated hierarchy of simplicial triangulations. The mesh adaptivity relies on a residual-type a posteriori error estimator featuring face and element residuals. Both the components of the estimator and certain oscillation terms, due to the occurrence of the variable coefficients, have to be controlled properly within the adaptive loop which is taken care of by appropriate bulk criteria. Convergence of the AEFEM in terms of reductions of the energy norm of the discretization error and of the oscillations is shown. Numerical results are given to illustrate the performance of the AEFEM.

IC/MP166/027: Multigrid methods for systems of PDEs.

Organiser: Marcus Mohr (Universität München, Germany)
Co-organiser: Ulrich Rüde (Universität Erlangen-Nürnberg, Germany)

The last two decades have seen a steady increase in the interest in so called multigrid and mutilevel approaches for the solution of linear systems of equations arising from the discretisation of models described by partial differential equations. This phenomenon is primarily based on two factors. On the one hand side there is a constant growth in size and complexity of such models. On the other side optimally tuned multigrid methods can solve the associated linear systems with an amount of work that scales linearly with the number of unknowns. Making them especially interesting not only for stationary linear problems, but also for non-linear and time-dependent ones. Thus, multilevel methods have long transcended the realm of symmetric and positive definite problems for which they were originally designed.

However, in order to reach optimal convergence rates the individual components of a multilevel algorithm must always be adapted to the problem at hand. This can either be done manually for a concrete application or by automatic techniques as in blackbox and algebraic multigrid approaches. Systems of PDEs pose their very own challenges in this respect. Be it that many such applications are formulated as saddle point problems and the resulting indefinite linear algebraic problems require the classical point smoothers to be replaced by coupled or distributive relaxation approaches to reduce high-frequency error components. Be it that new methods are required in order to identify coarse error components and to construct coarse 'grids' in algebraic approaches for systems. Be it that schemes for the construction of operator dependent grid transfers in the case of strongly varying or jumping coefficients must be adapted from the scalar to the system setting.

This minisymposium aims at bringing together researchers from the multilevel community and from application areas where these methods are applied to systems of PDEs in order to present and discuss new concepts and ongoing research in this field. The talks will cover a broad range of applications and approaches ranging from geometric methods for systems resulting from the Finite Element discretisation of the generalised Stokes problem of geophysical mantle convection over multigrid methods applied to the poro-elasticity problem used for Finite Differences on staggered and collocated grids up to new approaches for systems in algebraic multigrid methods and problems in the new application area of image processing and optical flow.

Multigrid methods for the poroelasticity system. **Francisco Gaspar** (Universidad de Zaragoza, Spain), Lisbona Francisco (Universidad de Zaragoza, Spain), Cornelis Oosterlee (TU Delft, The Netherlands) IC/MT2972/027

In this talk, we present robust and efficient multigrid solvers for the poroelasticity system. We introduce a reformulation of the problem which enables us to treat the system in a decoupled fashion. This permits us to choose a highly efficient multigrid method for a scalar Poisson type equation for the overall solution of this poroelasticity system. With standard geometric transfer operators, a direct coarse grid discretization and a point-wise red-black Gauss-Seidel smoother, an efficient multigrid method is developed for all relevant choices of the problem parameters. The transformation boils down to a stabilization term in the original formulation for which a highly efficient multigrid solver also can be developed. A relation between the multigrid treatment of poro-elasticity and the Stokes equations is also included in this talk.

Generation of coarse-grid approximations for systems of PDEs with discontinuous coefficients. **Marcus Mohr** (Universität München, Germany), Harald Köstler (Universität Erlangen–Nürnberg, Germany), Ulrich Rüde (Universität Erlangen–Nürnberg, Germany) IC/MT1414/027

Multigrid methods are well-known for combining fast convergence speeds with low costs per individual iteration step when applied for the solution of linear systems arising from elliptic partial differential equations (PDEs). However, in order to reach the ultimate goal of linear $\mathcal{O}(n)$ efficiency for solving such problems the interplay of the individual components that make up a multigrid method must be optimal. In detail these components are smoother, grid coarsening strategy, inter-grid transfer operators and the coarse grid approximation of the fine grid operator.

This talk considers the construction of the latter component for the special situation that the linear system under consideration stems from the discretisation of a system of PDEs and features strongly varying or discontinuous coefficients. This situation arises in many practical applications, e.g. optical flow reconstruction in image processing or simulation of mantle convection in geophysics. We report on different approaches that extend the classical techniques for the case of scalar-valued stencil coefficients to the case of tensor-valued entries and present examples from the two application fields mentioned above.

Coarse-grid selection for systems of PDEs based on compatible relaxation. **Robert Falgout** (Lawrence Livermore National Laboratory, USA) IC/MT2581/027

Algebraic multigrid is an important method for solving the large sparse linear systems that arise in many PDE-based scientific simulation codes. A major component of algebraic multigrid methods is the selection of coarse grids.

The notion of *compatible relaxation* (CR) was introduced by Brandt in [1] as a modified relaxation scheme that keeps the coarse-level variables invariant. Brandt states that the convergence rate of CR is a general measure for the quality of the set of coarse variables, and in [2], we developed a supporting theory for this idea. We have since developed an algebraic coarsening algorithm based on compatible relaxation that has several nice properties over the classical coarsening schemes. One such characteristic is its ability to ensure the quality of the coarse grid. However, our original method has the potential to overselect coarse-grid points when applied to PDE systems problems.

In this talk, we will describe recent progress developing a systems version of our coarsening algorithm, point out its current strengths and weaknesses, and discuss open questions and future directions.

This work was performed under the auspices of the U.S. Department of Energy by University of California Lawrence Livermore National Laboratory under contract No. W-7405-Eng-48.

IC/MP650/027: Adaptive and multilevel methods: design, analysis, and application.

Organiser: Ricardo Nochetto (University of Maryland, USA)
Co-organiser: Jinchao Xu (Pennsylvania State University, USA)
Co-organiser: Kunibert Siebert (Universität Augsburg, Germany)

This minisymposium will explore a more complete integration of adaptive and multilevel algorithms, in terms of algorithm design, convergence and complexity theory, and application to important problems in science and engineering. This endeavor is expected to foster the theoretical foundations for the combined use of modern techniques in adaptivity and multilevel solvers, leading to general principles and guidelines for designing and applying adaptive and multilevel algorithms in an integrated fashion, with the goal of improving the effectiveness of mult-ilevel adaptive methods in various applications. This combination of theoretical and algorithmic design framework will be positioned to have substantial impact in the multiscale/multiphysics modeling areas, which draw on ideas from both the multilevel and adaptivity areas independently. Since applications truly drive the research in multiscale modeling, the list of tentative speakers reflects our intent of mixing basic research with applications as well as numerical techniques such as adaptive finite elements methods (AFEM) with wavelets.

A list of fundamental challenges to be discussed in the minisymposium follows:

- Convergence and optimality of AFEM for general elliptic operators.
- Multigrid methods for PDE with discontinuous and degenerate coefficients. Anisotropic refinement/coarsening.
- Algebraic multigrid for AFEM: design and convergence analysis.
- Parallel AFEM: design, convergence, and optimality.
- AFEM and wavelets for nonlinear PDE.
- AFEM for geometric flows: design and analysis.
- Multilevel AFEM for porous media and complex fluids.

A basic convergence result for conforming adaptive finite elements. **Andreas Veeser** (Università degli Studi di Milano, Italy), Pedro Morin (Universidad Nacional del Litoral, Argentina), Kunibert Siebert (Universität Augsburg, Germany) IC/MT2739/027

We consider the approximate solution with adaptive finite elements of a class of linear boundary value problems, which includes problems of 'saddle point' type. Supposing that refinement relies on unique quasi-regular element subdivisions and leads to locally quasi-uniform grids, that the finite element spaces are conforming, nested, and satisfy the inf-sup conditions, that the error estimator is reliable as well as locally and discretely efficient, and that marked elements are subdivided at least once, we give a sufficient and essentially necessary condition on marking for the convergence of the finite element solutions to the exact one. This condition is not only satisfied by Dörfler's strategy, but also by the maximum strategy and the equidistribution strategy.

An optimal adaptive finite-element method. **Rob Stevenson** (Universiteit Utrecht, The Netherlands) IC/MT2373/027

We present a construction an adaptive finite element method for solving elliptic equations in d space dimensions that has optimal computational complexity. Whenever for some $s > 0$, the solution can be approximated to accuracy $\mathcal{O}(N^{-s})$ in energy norm by a continuous piecewise polynomial of degree k on some partition into N d-simplices, and one knows how to approximate the right-hand side in the dual norm with the same rate with piecewise polynomials of degree $k-1$, then the adaptive method produces approximations that converge with this rate, taking a number of operations that is of the order of the number of simplices in the output partition. The method is similar in spirit to that from [*SINUM*, 38 (2000), pp.466–488] by Morin, Nochetto, and Siebert, and so in particular it does not rely on a recurrent coarsening of the partitions.

When time allows, as extensions we discuss a new optimal goal oriented adaptive finite element method, and such a method for solving the Stokes equations, and illustrate our findings with numerical results.

Convergence and optimality of AFEM for general second-order linear elliptic operators. **Ricardo Nochetto** (University of Maryland, USA), Kunibert Siebert (Universität Augsburg, Germany) IC/MT3799/027

We analyze the simplest and most standard adaptive finite element method (AFEM), with any polynomial degree, for general second order linear, symmetric elliptic operators. As it is customary in practice, AFEM marks exclusively according to the error estimator and performs a minimal element refinement without the interior node property. We prove that AFEM is a contraction for the sum of energy error and scaled error estimator, between two consecutive adaptive loops. This geometric decay is instrumental to derive optimal cardinality of AFEM. We show that AFEM yields a decay rate of energy error plus oscillation in terms of number of degrees of freedom as dictated by the best approximation for this combined nonlinear quantity. This is joint work with J.M. Cascon, C. Kreuzer, and K.G. Siebert.

A new class of anisotropic smoothness spaces. **Ronald DeVore** (University of South Carolina, USA) IC/MT3740/027

We introducee a new class of smoothness spaces based on the level sets of a function. These spaces can already be shown to effectively describe images which can be well compressed. They could potentially be useful in constructing and analyzing adaptive methods for nonlinear evolution equations because of their anisotropic character. We will describe these spaces and some of their properties.

IC/MP650/027: Adaptive and multilevel methods: design, analysis, and application. #2

Regular decompositions and multigrid analysis. **Ralf Hiptmair** (ETH Zürich, Switzerland) IC/MT3735/027

Regular decompositions provide stable splittings of Sobolev spaces of div- and curl-conforming vector fields into an H^1-regular component and a contribution from the kernel of the differential operator. It has turned out that these decompositions hold the key to regularity-free multigrid theory for discrete $\mathbf{H}(\mathrm{curl},\Omega)$- and $\mathbf{H}(\mathrm{div},\Omega)$-elliptic variational problems. They have also inspired the construction of new auxiliary space methods. The talk will give a survey of regular decompositions and explain how they pave the way for harnessing the power of multilevel theory in H^1 for vector-valued variational problems.

Hierarchical error estimates for contact problems. **Ralf Kornhuber** (Freie Universität Berlin, Germany), Oliver Sander (Freie Universität Berlin, Germany) IC/MT3804/027

Hierarchical error estimates are based on the solution of local subproblems associated with an enlarged trial space. In the linear self-adjoint case, the resulting error indicators are locally equivalent to well-known residual-based estimates. In this talk, we discuss recent extensions to contact problems in continuum mechanics.

Error reduction in adaptive finite-element methods for elliptic obstacle problems. **Ronald Hoppe** (Universität Augsburg, Germany) IC/MT2889/027

An *a posteriori* error analysis for finite element approximations of elliptic obstacle problems on the basis of residual and hierarchical type *a posteriori* error estimators has been provided in a series of papers. In this contribution, we are concerned with a convergence analysis of adaptive finite element methods. We are using a residual error estimator which is a slight modification of that known from the unconstrained case. The ingredients of the convergence analysis are the reliability of the estimator, its discrete local efficiency, and an appropriate bulk criterion for the refinement process. Numerical results are given to illustrate the performance of the estimator.

Convergent adaptive approximation of some nonlinear elliptic problems. **Michael Holst** (University of California, San Diego, USA) IC/MT3424/027

We examine two nonlinear PDE models arising in biophysics and geometric analysis. We begin by establishing basic results and max-norm estimates. We then derive *a priori* and *a posteriori* estimates for Galerkin approximations, and describe a nonlinear approximation algorithm based on error indicator-driven adaptive refinement. We then develop some convergence results for the adaptive algorithm applied to each nonlinear problems. We finish by illustrating the adaptive algorithm with examples using the Finite Element ToolKit (FETK).

Portions of this work are joint with Long Chen and Jinchao Xu.

IC/MP139/015: Recent advances in numerical multiscale methods.

Organiser: Giovanni Samaey (Katholieke Universiteit Leuven, Belgium)
Co-organiser: Dirk Roose (Katholieke Universiteit Leuven, Belgium)

For many problems, ranging from hydrodynamics to chemistry and mathematical biology, one can only model the system dynamics with sufficient accuracy by including effects on microscopic scales. Due to the computational complexity, direct simulation using standard numerical methods then quickly becomes prohibitively expensive. However, we are often only interested in the system dynamics on macroscopic scales.

Therefore, there is an active interest in developing *multiscale* numerical algorithms, which aim at bridging the gap between the (microscopic) scale at which a model is given, and the (macroscopic) scale at which we would like to observe and analyse the system. This minisymposium provides an overview of some recently developed methods.

The first session is devoted to the class of so-called *equation-free* methods, as proposed by Kevrekidis *et al.* This framework assumes that a closed model *exists* (conceptually) for an appropriate set of macroscopic observables, which cannot be derived explicitly from the underlying microscopic model without making simplifications that are hard to justify. The main idea is to design *computational experiments* with the microscopic model to estimate macroscopic time derivatives; these experiments replace function evaluations which would normally have been obtained using the macroscopic model. The speakers will discuss issues of initialization, accuracy and efficiency and show a number of applications.

The second session addresses numerical methods for multiscale partial differential equations. Due to small-scale heterogeneities, the system parameters often exhibit randomness; the aim is to obtain appropriate statistics of the behaviour on macroscopic scales. The speakers will discuss numerical upscaling techniques to obtain homogenised coefficients, uncertainty quantification, patch dynamics and algorithm refinement methods.

From microscopic to macroscopic behaviour in biological systems. **Radek Erban** (University of Oxford, UK) IC/MT688/0

We present analytical (derivation of macroscopic equations) and computational (macroscopic equation-free) approaches for extracting a population-level behaviour from individual-based models of biological systems. We consider systems of many individuals (molecules, cells, organisms) for which the stochastic individual-based (microscopic) models are given and we study their macroscopic (collective, coarse-grained) behaviour. The biological examples include dispersal of unicellular organisms (e.g. bacterium Escherichia coli or amoeboid cell Dictyostelium discoideum) and models of gene regulatory networks.

Analysis of the constrained-runs reduction scheme. **Antonios Zagaris** (CWI, Amsterdam, The Netherlands) IC/MT1865/0

Microscopic and detailed macroscopic modelling often leads to large systems whose dynamics occur in a broad range of time scales. Multiscale reduction methods exploit the time-scale disparity present in a system to derive a simplified description of it, which is valid after the short initial transients have relaxed and captures the eventual dynamics. In this way, numerical stiffness may be removed and simulation times radically decreased, thus paving the way to the efficient modelling of many complex systems.

Recently, a family of reduction methods was proposed with the scope of assisting efficient, equation-free implementations of the projective integration schemes developed by C.W. Gear and I.G. Kevrekidis. These methods have also found application in hybrid modelling—in particular, in matching the state variables used in different spatial regions across the interface smoothly. In this talk, I will identify the principle underlying these methods and examine its accuracy in the context of singularly-perturbed dynamical systems. Further, I will consider simple computational realizations of these methods and examine analytically their stability properties. I will conclude with a short discussion of possible stabilization schemes and other future extensions of this work.

This is joint work with: C.W. Gear, I.G. Kevrekidis, and T.J. Kaper.

Numerical analysis of the accelerated coarse time-stepper for a lattice-Boltzmann model. **Christophe Vandekerckhove** (Katholieke Universiteit Leuven, Belgium), Dirk Roose (Katholieke Universiteit Leuven, Belgium) IC/MT3168/0

In current modelling practice, the best available model is often given on a microscopic level, while one is only interested in the coarser, macroscopic behaviour of the system. For this class of problems, Kevrekidis and coworkers have developed the equation-free computing approach, which uses appropriately initialized microscopic simulations to perform traditional macroscopic tasks, hereby circumventing the theoretical derivation of macroscopic evolution equations.

The basic tool is the so-called coarse time-stepper. An essential component is the lifting step in which a macroscopic field is mapped to the higher-dimensional space of microscopic variables. As this lifting step is not unique, it is often non-trivial to implement. In this context, the constrained runs algorithm was proposed to compute an appropriate microscopic state. The purpose of this talk is to study several aspects of the equation-free approach for a lattice Boltzmann model of a reaction-diffusion system. We first show how the lifting influences the accuracy and the stability of the resulting coarse time-stepper. Then, we show that, depending on the model parameters, the constrained runs iteration may converge very slowly or that it may even diverge. An alternative implementation based on a preconditioned Newton-Krylov method is therefore presented and tested for the lattice Boltzmann model. Finally, we demonstrate that once an appropriate coarse time-stepper is constructed, it can be accelerated substantially using the recently proposed teleprojective integrators or the multistep state extrapolation method.

Coarse-grained computations for agent-based models. **Yannis Kevrekidis** (Princeton University, USA) IC/MT3034/0

We will discuss recent advances in equation-free computation of fine-scale models. In particular, we will study how equation-free methods can be linked to data mining algorithms for the on-line "discovery" of good coarse-grained observables.

IC/MP139/015: Recent advances in numerical multiscale methods. #2

Co-organiser: Dirk Roose (Katholieke Universiteit Leuven, Belgium)

(For abstract, see session #1 above.)

Patch dynamics: macroscopic simulation of multiscale systems. **Giovanni Samaey** (Katholieke Universiteit Leuven, Belgium), Yannis Kevrekidis (Princeton University, USA), Dirk Roose (Katholieke Universiteit Leuven, Belgium) IC/MT1822/0

For an important class of multiscale problems, a separation of scales exists between the available (microscopic) model and the (macroscopic) level at which one would like to observe and analyze the system. For time-dependent multiscale problems of this type, Kevrekidis et al. developed a so-called "equation-free" framework, based on the idea of a so-called coarse-grained time-stepper. The patch dynamics scheme is a coarse-grained time-stepper which approximates the time evolution of a set of spatially distributed macroscopic variables for which the governing partial differential equation (PDE) is not (or only approximately) available; the scheme only performs appropriately initialized simulations using the available microscopic model in small portions of the space-time domain (the patches).

We present some theoretical and numerical convergence results for a class of parabolic homogenization problems. In particular, we show that the scheme approximates a finite difference scheme for the unavailable macroscopic equation. We also formulate and analyze a finite volume variant, and discuss some issues that arise when trying to combine patch dynamics with adaptive mesh refinement (AMR). We conclude with a brief discussion of the possibilities and limitations of the current schemes, and provide some ideas for future research.

Modeling of fluctuations in algorithm refinement methods. **John Bell** (Lawrence Berkeley National Laboratory, USA) IC/MT1480/0

We consider an approach for hybrid algorithms based on an adaptive mesh refinement paradigm. In this approach a hierarchical adaptive mesh refinement framework is used to embed a particle algorithm within the finest grid of the mesh hierarchy. The coupling between the particle region and the overlaying continuum grid is functionally equivalent to that between fine and coarse levels of mesh refinement. In this paper we consider the role of fluctuations in this type of hybrid algorithm. In particular, we discuss the impact of fluctuations on the dynamics. We demonstrate that it is necessary to include a stochastic forcing term to model fluctuations at the continuum level to accurately capture the correct behavior of the system. We illustrate the role of fluctuations on two model problems. In the first we consider an excluded random walk model whose mean field behavior is given by the viscous Burgers' equation. The second example discusses a hybrid of direct simulation Monte Carlo with the compressible Navier Stokes equations. For the Navier Stokes equations we include stochastic fluxes as given by Landau-Lifshitz fluctuation Navier-Stokes equations.

Equation-free methods for molecular dynamics: a lifting procedure. **Yves Frederix** (Katholieke Universiteit Leuven, Belgium), Dirk Roose (Katholieke Universiteit Leuven, Belgium) IC/MT5043/0

The equation-free framework as proposed by Kevrekidis *et al.* offers a methodology to compute the macroscopic system dynamics using only a description on the microscopic level. This technique is especially suitable when the macroscopic equations are unknown or cannot be derived in a closed form. Short bursts of the microscopic simulation code are combined with appropriate lifting (initialization) and restriction (averaging) operators to cross the boundaries between micro- and macroscopic scale. The resulting time integrator defines the so-called coarse time stepper and enables the microscopic code to perform system-level tasks.

In this work we use molecular dynamics as the microscopic simulator and investigate the difficulties that can arise when using this type of microscopic description. An important issue is the appropriate initialization of the microscopic simulator in order to obtain the correct coarse dynamics. We will define good lifting and restriction operators, based on kernel density estimation, which are suited for use in the equation-free framework. We present a model problem where we aim at calculating a coarse steady state of a time evolving probability density function, and use it as an illustration for the proposed operators.

IC/MP695/027: *A posteriori* error estimates and multi-grid methods for eigenvalue problems.

Organiser: Ludmil Zikatanov (Pennsylvania State University, USA)
Co-organiser: Daniele Boffi (Università degli Studi di Pavia, Italy)

The main theme of the minisymposium is on the advanced finite element and multigrid techniques for eigenvalue problems. The focus is on the *a posteriori* error estimation and the design of adaptive tools both at the discretization stage and for the solution of the resulting large-scale linear and nonlinear discrete problems. Examples of potential applications of these techniques are found in numerical models used in electromagnetics, flow simulation, elasticity and quantum chromodynamics and other.

Towards adaptive multigrid eigenvalue computation. **Carsten Carstensen** (Department of Mathematics Humboldt-Universität, Germany), Ira Livshits (Ball State University, USA) IC/MT3640/027

The presentation concerns the effective and reliable computation of PDE eigenvalue computation of model problems with adaptive mesh-refining algorithms and fast multigrid solvers. The reliable *a posteriori* error control of some finite element discretisation is reviewed from the literature. The approaches by Rannacher et al. and Larsson et al. are compared and some illustrative adaptive finite element cacluations will be presented. Multigrid methods have shown to be efficient for solving a variety of eigenvalue problems by exploiting different smoothness properties of operators and solutions. They are also benefitial for fast and accurate evaluation of global properties: such as eigenvalues, and this makes them even more attractive for the task. In this talk we discuss the current developments in the field of multigrid solvers for eigen problems, including an idea of multiscale eigenbasis that allows fast approximation of many eigenfunctions at once.

Multigrid/multiscale approach for finding a full eigen-basis of differential operators. **Ira Livshits** (Ball State University, USA) IC/MT4910/027

In this talk we will discuss how to apply multigrid methods to the discretized differential eigenvalue problems if the goal is to find not one but rather all eigenfunctions and eigenvalues of the finest discrete operators. The challenge here is to allow representation of all such eigenfunctions on the increasingly coarser grids, and do it accurately. The proposed solver uses the Multigrid Eigenbasis (MEB) structure for eigenfunction representation and employees special types of prolongation and restriction operators. The strategies of choosing such operators will be discussed on different examples, in particular, the Schrodinger eigenvalue problem. Numerical experiments and discussion of possible extensions of presented results conclude the talk. (Joint work with Achi Brandt.)

Mixed approximation of eigenvalue problems: a super-convergence result. **Daniele Boffi** (Università degli Studi di Pavia, Italy), Francesca Gardini (Università di Pavia, Italy) IC/MT3981/027

In this talk we present a superconvergence result for the lowest-order Raviart-Thomas approximation of eigenvalue problems. It is well-known that a similar superconvergence property holds for the mixed approximation of Laplace problem.

Here we introduce a new proof, since the one given for the source problem cannot be generalized in a straightforward way to the eigenvalue problem. Indeed, the key point of the proof strongly relies on the Galerkin orthogonality, which holds for the source problem but not for the eigenvalue one.

In order to prove the superconvergence property we will use the equivalence between the lowest order Raviart-Thomas approximation of Laplace eigenproblem with Neumann boundary conditions and the non-conforming piecewise linear Crouziex-Raviart approximation. We will also make use of a superconvergence result proved by Duran et al. for Laplace eigenproblem with Dirichlet boundary conditions.

Using this result, we introduce a reliable and efficient *a posteriori* error estimator for the lowest order Raviart-Thomas approximation of Laplace eigenproblem.

Eventually, we will show some numerical experiment which confirm the superconvergence property and suggest that it also holds for the lowest order Brezzi-Douglas-Marini approximation.

An adaptive multigrid method for the Dirac equations in lattice QCD. **James Brannick** (Pennsylvania State University, USA) IC/MT4004/027

Classical multigrid (MG) methods assume explicit knowledge of so-called algebraically-smooth or near-kernel components, which loosely speaking are errors that give relatively small residuals. Tyically, these methods generate a sequence of coarse spaces under the assumption that the near-kernel is locally constant. The difficulty in applying MG to discretizations of Quantum Chromodynamics (QCD) on a lattice is that the near-kernel components of the resulting Dirac matrix can be far from constant, often exhibiting little or no apparent smoothness. In fact, the local character of these components is random, depending on the randomness of the gluon fields. As a result, no apriori knowledge of the local character of the near-kernel of the Dirac operator is readily available.

In this talk we present a recently developed complex-arithmetic adaptive MG preconditioner suitable for the linear systems arising in lattice QCD. The method is an extension of the adaptive smoothed aggregation iterative solver in which good convergence properties are achieved in situations where explicit knowledge of the near-kernel components are not available. This extension is accomplished using the method itself to define a multilevel power iteration to expose the near-kernel. The coarsening process is then modified to both use and improve these computed components. Numerical results are presented to demonstrate the efficacy of the method.

IC/MP527/028: From differential geometry to compatible discretization.

Organiser: Ralf Hiptmair (ETH Zürich, Switzerland)
Co-organiser: Douglas Arnold (University of Minnesota, USA)

Recent years have seen tremendous progress in the transfer of ideas and concept from differential geometry to the discrete realm. Yet, we are only at the beginning of a development that has had and will have a powerful impact in areas as diverse as numerical methods for ordinary and partial differential equations and computer graphics.

This minisymposium aims to bring together leading researchers who have worked on various aspects of discrete differential geometry and related compatible discretizations. Their presentations will provide a survey of this exciting development, illuminating it from different perspectives and from different areas of application.

Discrete calculus of chainlet theory. **Jenny Harrison** (University of California, Berkeley, USA) IC/MT3972/028

This talk concerns the "missing half" of calculus – the study of k-dimensional domains of integration in n-space called "chainlets" matching the classical calculus of functions and forms. The chainlet operators, products and integrals apply to both symmetric and antisymmetric tensors yielding the full calculus on Euclidean space, cell complexes, manifolds with corners and cusps, bilayer structures (e.g., soap films), and nonsmooth domains such as fractals with equal ease. The resulting theory unifies and extends several classical viewpoints, from the discrete simplicial complex to the continuum theory of the exterior calculus. As time permits, we shall discuss applications to differential geometry and particle physics.

Discrete mechanics, DEC and optimization. **Jerrold Marsden** (California Institute of Technology, USA) IC/MT4807/028

This talk will present some work on discrete mechanics, differential exterior calculus and optimization. The DEC work concerns electromagnetism, the Yee scheme and its generalization to nonregular meshes, following Bossavit and others. The optimization work concerns the use of discrete mechanics together with SQP methods to solve optimization problems in robotics and satellite reorientation, for example.

Joint work with Mathieu Desbrun, Ari Stern, Sigrid Leyendecker and others.

Smoothed projections in finite-element exterior calculus. **Ragnar Winther** (Universitetet i Oslo, Norway) IC/MT2629/028

A classical problem in the analysis of mixed finite element methods is that the canonical interpolation operators onto the finite element spaces are not bounded with respect to the natural Sobolev norm. As a consequence, additional properties like extra regularity have to be introduced to establish stability. In this talk we will discuss how this problem can be avoided by constructing so-called smoothed projections, and how the properties of these operators lead directly to various stability properties of the corresponding discretizations of the Hodge-Laplace problem.

Smooth bases for discrete exterior calculus through subdivision. **Peter Schröder** (California Institute of Technology, USA) IC/MT4846/028

The basic approach to discrete exterior calculus on simplicial meshes in effect amounts to the use of certain linear finite elements (Whitney elements) when seen from a FEM point of view. A natural question then is whether one can exhibit smoother bases. One avenue is local enrichment with higher order polynomials. This leads to constructions in which multiple degrees of freedom *live* at simplicies of several dimensions for each of the underlying form fields. Instead we chose to go a different route. Fixing the simplicial co-boundary operator as the discrete d and demanding that there continue to be only single degrees of freedom per simplex, we produce smoother bases (with somewhat larger support) through subdivision. The resulting bases can be seen as generalizations of certain spline constructions. Since they are refinable they also come with attractive multigrid properties. In my presentation I will give a brief introduction to subdivision; i.e., the construction of

smooth functions (forms) through refinement and then discuss the central idea in our construction: ensuring that the subdivision operators commute with the discrete d.

Knotted linear force-free magnetic fields: topological aspects. **P. Robert Kotiuga** (Boston University, USA) IC/MT3592/028

Force-free magnetic fields, that is current distributions with vanishing Lorentz force, can be constructed from the eigenfunctions of the curl operator. A key obstacle is that when vector fields are restricted to be solenoidal, and the region of interest is restricted to be a compact manifold with boundary, the boundary conditions which render the curl and curl-curl operators self-adjoint, are mutually exclusive. Therefore, one cannot directly exploit the experience gained in electromagnetic cavity resonator calculations in the eigenvalue problem for the curl operator. Early calculations of linear force-free magnetic fields considered unbounded domains and sidestepped this problem by doing so. Later authors considered simply connected regions or unknotted multiply-connected regions. In more recent work a general study of self-adjoint curl operators is undertaken within a framework which accounts for knotted domains associated with the conjectured topological characteristics of force-free mgnetic fields. A caveat in finding boundary conditions which render the curl operator self-adjoint on a compact multiply-connected domain, is that the they are neccessarily nonlocal. Fortunately, the nonlocality can be articulated in terms of a symplectic form on the first homology group of the boundary, and handled systematically.

In this presentation, we formulate the b.v.p., emphasize the role of isotopy-invariant boundary conditions on multiply connected domains, and introduce notions from low-dimensional topology, such as the Torelli group, which articulate the difference between intuitive but noncomputable, versus formal but computable, aspects of formulating a well-posed b.v.p. on knotted domains.

Geometric discretisation of Einstein's equations. **Jörg Frauendiener** (Universitetet i Oslo, Germany) IC/MT4841/028

Einstein's theory of gravity is a geometric theory. It describes a gravitating system as a Ricci-flat Lorentzian manifold. As such it is invariant under diffeomorphisms which implies that individual points have no physical meaning. Only relations between several points are physically and geometrically meaningful. In this talk I present an approach to computational GR which is based on a discrete formulation of a geometry i.e., on quantities defined on higher dimensional structures. We show that one can reproduce exact spherically symmetric solutions of Einstein's equations and plane waves.

Application of finite-element exterior calculus to elasticity. **Richard Falk** (Rutgers University, USA) IC/MT4842/028

It is now understood that there is a close connection between finite element differential complexes and the stability of finite element methods for the approximation of a wide variety of systems of partial differential equations. By exploiting a connection between a differential complex related to the equations of elasticity and the de Rham complex, we show how a new simple class of stable finite element approximations for the equations of elasticity can be developed.

Compatible discretization for the Helmholtz equation. **Joachim Schöberl** (RWTH Aachen, Germany) IC/MT3174/028

This talk addresses the finite element discretization of resonance problems. The PML method is applied to truncate the originally unbounded domain at a finite radius. As it is well know, the PML method introduces artificial eigenvalues which depend on the PML parameter. Additional spurious eigenvalues are introduced by a conforming finite element discretization. In contrast to the PML eigenvalues, these FEM eigenvalues are not well separated from the physical ones. By mesh refinement, or by increasing the polynomial order of the finite elements, the spurious eigenvalues near the real axis can be reduced. This is a quantitative improvement.

In this talk we present a finite element method which avoids the spurious FEM eigenvalues. In the one dimensional case, the modified method can be implemented by an integration formula of reduced order. We propose a mixed method which can be applied also for the two and three dimensional case. We will present numerical examples, and the current, not yet complete state of the analysis.

IC/MP357/015: Numerical methods for data-assimilation problems.

Organiser: Angelika Bunse-Gerstner (Universität Bremen, Germany)
Co-organiser: Nancy Nichols (University of Reading, UK)

For the very large systems that arise in the environmental sciences, the available data are not sufficient to initiate a complex computational forecasting model. The technique of data assimilation enables measured observations (over time) to be combined with model predictions to generate accurate estimates of the system states, both current and future. The problem of data assimilation is essentially an ill-posed inverse problem. An overview of data assimilation will be presented here and the major types of assimilation method for treating very large nonlinear systems will be described. New numerical techniques for improving the computational efficiency of these procedures will be presented and some practical applications from atmosphere and ocean modelling will be discussed.

Overview of data assimilation and the application of model reduction for optimal-state estimation in very-large systems. **Nancy Nichols** (University of Reading, UK) IC/MT3838/015

The problem of data assimilation can be treated either by sequential techniques based on optimal filtering methods, or by variational techniques that aim to solve an optimization problem subject to a set of dynamical system equations. For the very large inverse problems arising in the prediction of atmosphere and ocean circulations and other environmental systems, these methods are too costly to be used for real-time forecasting, and approximations are needed for computational efficiency. In this talk, we will give a brief overview of the data assimilation methods currently applied in practice and describe some current research issues. Model reduction techniques from control theory provide an attractive method for improving the computational efficiency of data assimilation schemes. Recently we have investigated the use of reduced order models with Gauss-Newton iteration for solving four-dimensional variational data assimilation problems. Results obtained using a balanced-truncation model reduction method in a simple shallow water test case are presented. The results illustrate the superior performance of this approach and show that the same accuracy in the solution can be obtained more efficiently by model reduction than by the standard procedures.

For the very large unstable models arising in environmental systems, however, the balanced-truncation method is not suitable and new techniques are needed to enable this approach to be applied. In the subsequent papers in this mini-symposium, this issue and other new assimilation techniques are discussed. *This work is joint with A.S. Lawless of the University of Reading, UK, and C. Boess and A. Bunse-Gerstner of the University of Bremen, Germany.

Interpolation-based model reduction for data assimilation. **Angelika Bunse-Gerstner** (Universität Bremen, Germany) IC/MT3851/015

The first talk in this mini-symposium shows that model reduction methods can in fact improve the computational efficiency of data assimilation schemes. They decrease the computational complexity considerably by generating reduced order linear dynamical systems which behave similar to the linearisations of the model for the environmental systems used within the Gauss–Newton iteration steps. To make this approach feasible for realistic problems we need model reduction methods which can handle the very large dimensions of the original very large dynamical systems. Numerical methods based on rational interpolation via Krylov space projections are attractive for these very large dimensions. There one would like to choose the interpolation points such that the behaviour of the reduced system is a reasonable overall approximation to the corresponding original system. In this talk we give a brief survey on rational interpolation methods as well as their generalization to tangential interpolation to point out the computations needed for these interpolation based reductions. Necessary conditions for so-called H_2-optimal model reduction are shown, from which we derive a good choice of interpolation points to get reasonable approximations.

This work is joint with Dorota Kubalinska of the University of Bremen, Germany.

Unbiased square-root ensemble filters for high-impact weather prediction. **Sarah Dance** (University of Reading, UK) IC/MT562/015

Numerical weather prediction models require an estimate of the current state of the atmosphere as an initial condition. Observations only provide partial information, so they are usually combined with prior information, in a process called data assimilation. The dynamics of hazardous weather such as storms is very nonlinear, with only a short predictability timescale, thus it is important to use a nonlinear, probabilistic filtering method to provide the initial conditions. Unfortunately, the state space is very large (about 10^7 variables) so approximations have to be made. The ensemble square root filter is a quasi-linear filter that has recently been proposed in the meteorological and oceanographic literature to solve this problem. The filter uses a forecast ensemble (a Monte Carlo sample) to estimate the prior statistics. In this talk we will describe the ensemble filter framework and some of its strengths and weaknesses. In particular we will demonstrate a new result that not all filters of this type bear the desired relationship to the forecast ensemble: there can be a systematic bias in the analysis ensemble mean and consequently an accompanying shortfall in the spread of the analysis ensemble as expressed by the ensemble covariance matrix. This points to the need for a restricted version of the notion of an ensemble square root filter. We have established a set of necessary and sufficient conditions for the scheme to be unbiased. Whilst these conditions are not a cure-all and cannot deal with independent sources of bias such as modelling errors, they should be useful to designers of ensmeble filters in the future. Work done in collaboration with Nancy Nichols and David Livings at the University of Reading. Work supported in part by the NERC National Centre for Atmospheric Sciences, an RCUK Academic Fellowship and by the NERC Data Assimilation Research Centre.

Variational assimilation of Lagrangian data in oceanography. **Maëlle Nodet** (Université Grenoble I, France) IC/MT3841/015

Within the framework of Global Ocean Data Assimilation Experiment (GODAE), an increasing amount of data are available. A crucial issue for oceanographers is to exploit at best these observations, in order to improve models, climatology, forecasts, etc. Thanks to the international program Argo and to more localized experiments (such as SAMBA, ARCANE-Eurofloat, ACCE), a new type of data is now available: positions of floats drifting at depth in the ocean. Unlike other data, mainly Eulerian, these ones are Lagrangian: the measuring instrument move in the flow. I will present methods and results about 4D-Var assimilation of Lagrangian data in the OPAVAR ocean model: implementation, sensitivity studies, assimilation of noisy observations, comparison with a classical method, complementarity with temperature data.

IC/MP102/015: Complexity of high-dimensional problems.

Organiser: Josef Dick (UNSW Asia, Singapore)
Co-organiser: Frances Kuo (University of New South Wales, Australia)

Tractability of high dimensional problems is an important criterion for deciding whether a problem can be solved within a reasonable time and effort. High dimensional problems occur often in applications and provide many challenging tasks even for nowadays computers. Hence the analysis of the inherent complexity of high dimensional problems becomes an interesting important topic.

Generalized tractability of multivariate problems. **Henryk Woźniakowski** (University of Warsaw, Poland) IC/MT1293/015

There is an increasing interest in solving multivariate problems of d variate functions with huge d. In this case, it is necessary to study how the errors of algorithms also depend on d. Polynomial tractability requires that the minimal error of algorithms using n function values or linear functionals depends at most polynomially on d and go to zero polynomially in n^{-1}. Generalized tractability may relax this requirement by admitting more than polynomial dependence which is, however, non-exponential.

We show for selected multivariate problems, such as integration and approximation, necessary and sufficient conditions for generalized tractability in terms of the properties of the underlying spaces defining the problem.

The worst-case error of (t,s)-sequences for integration in certain Hilbert spaces. **Peter Kritzer** (Universität Salzburg, Austria), Friedrich Pillichshammer (Universität Linz, Austria) IC/MT1165/015

We study the worst case error for quasi-Monte Carlo integration of functions from certain weighted Hilbert spaces which are based on Walsh functions. It has been shown recently that this worst case error is closely linked to a measure for the irregularity of distribution of a point set in the s-dimensional unit cube, namely the so-called dyadic diaphony as introduced by Hellekalek and Leeb in 1997. It is known that a sequence of points in $[0,1)^s$ is uniformly distributed modulo one if and only if the dyadic diaphony of the first N elements of the sequence converges to zero as N goes to infinity. A well-known example of such uniformly distributed sequences are (t,s)-sequences as introduced by Niederreiter in 1987.

We give an overview of recent results, and discuss bounds on the worst case error in the Walsh Hilbert spaces using digital (t,s)-sequences for quasi-Monte Carlo integration. Concerning the connection of the worst case integration error to the dyadic diaphony, we use our results to show that the dyadic diaphony of the first N elements of certain (t,s)-sequences in base 2 is of order $O(2^t(\log N)^{s/2}/N)$.

Lattice rules for integration over $\mathbb{R}^s$. **Stephen Joe** (University of Waikato, New Zealand) IC/MT4865/029

There has been much work done on lattice rules for the numerical approximation of integrals defined over the s-dimensional unit cube. If the integration region happens to be $\mathbb{R}^s$, it is quite common to apply some transformation to map $\mathbb{R}^s$ to the unit cube in order to make use of these lattice rules.
However, there do exist lattice rules for $\mathbb{R}^s$. For integrals over this unbounded region, the natural question that arises is whether such lattice rules have merit for the approximation of these integrals.

This talk is based on a joint work with Vasile Sinescu. We review some known results for these lattice rules and present some new preliminary theoretical results based on Fourier transforms and reproducing kernel Hilbert spaces.

QMC in multilevel Monte Carlo path simulation. **Michael Giles** (University of Oxford, UK) IC/MT5059/015

In this talk I will discuss the use of rank-1 lattice rules to further improve the computational complexity of multilevel Monte Carlo path simulation. Of particular interest is the fact that the QMC approach yields significant benefits on the coarsest (low-dimensional) levels, but very little benefit on the finest (high-dimensional) levels for which the multilevel technique has apparently already extracted most of the low-dimensional content.

Randomized algorithms and complexity for elliptic PDE. **Stefan Heinrich** (TU Kaiserslautern, Germany) IC/MT1256/015

We study the randomized information complexity of elliptic partial differential equations with smooth coefficients in smooth domains D of R^d. The right hand side is supposed to belong to the Sobolev space $W_p^r(D)$, the solution is sought on a submanifold M of D, and the error is measured in the norm of $L_p(M)$, where $r \in N$ and $1 \le p < \infty$. We obtain matching up to logarithmic factors upper and lower bounds. The results extend previous investigations of the $p = \infty$ case.
We discuss algorithms for special cases that reach the optimal rates. They involve, in particular, multilevel Monte Carlo methods for approximating weakly singular operators and their use in connection with Green's functions.

A new quadrature using integration lattices. **Xiaoyan Zeng** (Illinios Institute of Technology, USA) IC/MT1345/015

We propose a new quadrature rule via approximating Fourier coefficients of variable transformed integrand with multidimensional integration lattice. The error analysis is derived for the proposed rule. A comparison is done between the new rule and the periodizing transformation methods. It shown that the new rule improves the periodizing transformation methods.

In the last part, we provide a semi-optimal quadrature for weighted integrals whose integrand is in Banach space.

This is joint work with Fred J. Hickernell and Rong-Xian Yue.

Efficient randomized algorithm for L_∞ approximation over reproducing-kernel Hilbert spaces. **Grzegorz Wasilkowski** (University of Kentucky, USA) IC/MT1070/015

In this talk we will present a randomized algorithm for approximating functions from reproducing kernel Hilbert spaces with the error measured in L_∞-norm. Although the algorithm uses only function values, it enjoys the same rate of convergence as the optimal algorithm that uses optimal linear functionals for L_∞-approximation in the deterministic worst case setting.

Algorithms for L_∞ approximation in the worst case setting. **Frances Kuo** (University of New South Wales, Australia) IC/MT940/021

This is a joint work with Grzegorz Wasilkowski and Henryk Woźniakowski. We consider the problem of function approximation, with the error measured in L_∞-norm and analyzed in the worst case setting. Our aim is to establish how powerful (in terms of the rate of convergence) an algorithm which uses only function values can be, compared to the optimal algorithm that uses arbitrary linear functionals.

In this talk I will present general multilevel algorithms that

are half as powerful as the optimal algorithm, under certain assumptions on the function space. In the special case of weighted Korobov spaces, I will show that lattice rule algorithms can be tailored to further reduce this gap in power.

IC/MP319/015: Current advances in domain decomposition methods and an outlook into the future.

Organiser: Martin Gander (Université de Genève, Switzerland)
Co-organiser: Victorita Dolean (Université de Nice Sophia Antipolis, France)

Classical domain decomposition methods like the overlapping Schwarz method or Schur complement methods have reached a great level of maturity toward the end of the 20th century. Research in Domain Decomposition methods has however not decreased over the last decade, on the contrary. New methods have been developed with significantly enhanced performance, and because of the current hardware development, parallel computing is of more importance than ever before. If you are interested in getting an overview on recent developments in domain decomposition methods, this minisymposium is for you. Speakers will present new domain decomposition methods for evolution problems, in space-time or purely in time, new coupling conditions between subdomains for better performance or for nonconforming meshes, new finite element tearing and interconnect (FETI) variants, and will give an outlook into the future on how domain decomposition methods can be used to achieve petascale performance.

Dynamic contact problems with different time and length scales. **Corinna Hager** (Universität Stuttgart, Germany), Barbara Wohlmuth (Universität Stuttgart, Germany) IC/MT4213/015

Nonlinear frictional contact problems are still a challenging task both from the mathematical and engineering point of view, for example in the simulation and design of car tires. In this case, the additional difficulty occurs that the fine structure of the tire profile needs to be resolved accurately enough to analyse the evolution of the contact stresses and the temperature during rolling contact. To get an accurate result without unnecessary computational effort, the actual contact zone is to be simulated with a finer time resolution than the rest of the tire.

In this report, we consider an efficient and stable numerical algorithm for dynamical contact problems with different length scales in the time and space domain. We employ nonconforming overlapping domain decomposition in space to resolve details of the domain boundary by a fine mesh; further we are able to choose the time scale on the subdomain independent of the one of the coarse domain. We analyse different ways of coupling between the coarse and the fine grid in order to separate the subproblems.

The resulting frictional contact problem is solved by a primal-dual active set strategy which can be modified to result in an energy-conserving robust algorithm with good results for the contact stresses. Numerical results containing Coulomb friction and non-linear material laws illustrate the behavior of the scheme.

This work was supported in part by Manufacture Française des Pneumatiques Michelin.

Optimized Schwarz methods. **Martin Gander** (Université de Genève, Switzerland) IC/MT4990/029

Optimized Schwarz methods have been developed over the last decade for three reasons: to obtain Schwarz methods which converge without overlap, to obtain convergent Schwarz methods for physical problems where the classical Schwarz method is not convergent, and to enhance the converge speed of Schwarz methods in general. All this is achieved in optimized Schwarz methods by replacing the Dirichlet transmission conditions from the classical Schwarz method by differential transmission conditions adapted to the physics of the underlying problem. I will give an introduction to this subject with examples of elliptic and time dependent problems, which illustrate the effectiveness of this new approach. I will conclude with two important open research problems in optimized Schwarz methods.

The relation between optimized Schwarz methods for scalar and systems of partial differential equations. **Victorita Dolean** (Université de Nice Sophia Antipolis, France), Martin Gander (Université de Genève, Switzerland) IC/MT3666/015

Schwarz algorithms experienced a second youth over the last decades, when distributed computers became more and more performant and available. Fundamental convergence results for the classical Schwarz methods were derived for many partial differential equations. Optimized Schwarz methods have been developed for scalar partial differential equations in order to achieve high performance by using transmission conditions between subdomains adapted to the physical problem solved, and are convergent even without overlap. More recently, Schwarz methods have also been extended to systems of equations, and it was found that even the classical Schwarz method converges without overlap in certain cases. Using Maxwell's equations and their equivalence to associated scalar partial differential equations, we show why the classical Schwarz method converges without overlap in this case, by proving that it is equivalent to a simple optimized Schwarz method for a scalar equation. Using this link, we develop transmission conditions with better performance than just exchanging information following the characteristics for systems of hyperbolic partial differential equations.

Parareal in-time algorithm for fast resolution of PDEs. **Yvon Maday** (Université Pierre et Marie Curie, France) IC/MT3009/015

The parareal in time algorithm allows to perform parallel computations over different processors by decomposing the time evolution interval into non overlapping slabs. The initial values at the beginning of each slab is upgraded through a kind of predictor corrector iterative method.

After presenting the basics of the method, we shall present different realizations where the algorithm is either performed alone or coupled with some other iterative approaches like domain decomposition or optimal control techniques.

An important aspect of the method is related to the choice of the predictor, this aspect will be discussed together with the definition of appropriate combination of the predictor and corrector as far as stability issues are involved.

Scalable solver software from the DOE SciDAC program. **David Keyes** (Columbia University, USA) IC/MT2800/015

Towards Optimal Petascale Simulations (TOPS) is a scalable solver software project based on domain decomposed parallelization and sponsored by the U.S. Department of Energy to research, implement, and support in collaborations with scientific users an open-source package for large-scale discretized PDE problems. Current applications include fusion reactor and accelerator modeling and design, flows in porous media, and quantum chromodynamics. Optimal complexity methods, such as multigrid/multilevel preconditioners, keep the time spent in dominant algebraic kernels close to linear in discrete problem size as the applications scale on massively parallel computers. Krylov accelerators and Jacobian-free variants of Newton's method, as appropriate, are wrapped around the multilevel methods to deliver robustness in multirate, multiscale coupled systems, which are solved either implicitly or in more traditional forms of operator splitting. The TOPS software framework is being extended beyond direct computational simulation to computational optimization, including design, control, and inverse problems. We outline the capabilities TOPS offers to high-end simulations generally, and illustrate on applications.

TOPS includes co-principal investigators at Argonne National Laboratory, Lawrence Berkeley National Laboratory, Lawrence Livermore National Laboratory, Sandia National Laboratories, Columbia University, the University of California at Berkeley and at San Diego, the University of Colorado at Boulder, and the University of Texas at Austin, and is led by the speaker.

Exact and inexact FETI-DP algorithms with applications to elasticity. **Axel Klawonn** (Universität Duisburg-Essen, Germany), Patrizio Neff (TU Darmstadt, Germany), Oliver Rheinbach (Universität Duisburg–Essen, Germany), Stefanie Vanis (Universität Duisburg–Essen, Germany) IC/MT3121/015

In this talk, first an introduction to exact dual-primal FETI methods willbe given together with a motivation for the need of inexact methods if tens of thousands of processors or even more are used. An algorithmic framework for inexact FETI-DP methods will be presented; theoretical and numerical results will be shown for standard linear elasticity problems. New results of our ongoing research on FETI-DP algorithms for a linear elasticity problem with non-constant coefficientswill be also presented. This problem is part of a non-linear, coupled, micromorphic model for the description of foam or bone substitution materials.

FETI-DP and BDDC preconditioners for spectral-element discretizations of elliptic problems in 2D. **Luca Pavarino** (Università degli Studi di Milano, Italy), Axel Klawonn (Universität Duisburg-Essen, Germany), Oliver Rheinbach (Universität Duisburg–Essen, Germany) IC/MT2860/015

Domain decomposition methods of the FETI-DP and BDDC families, recently developed for standard finite element discretizations, are here extended to tensorial spectral elements discretizations based on GLL quadrature. In spite of the more severely ill-conditioned discrete systems, the resulting preconditioners are parallel and scalable, since their convergence rate is independent of the number of subdomains and only logarithmically dependent on the polynomial degree and the number of elements per subdomain. The results of numerical tests on parallel machines confirm these conclusions for scalar and vector elliptic problems in the plane.

Primal- and dual-interface concentrated iterative substructuring methods. **Ulrich Langer** (Universität Linz, Austria), Sven Beuchler (Universität Linz, Austria), Tino Eibner (TU Chemnitz, Germany) IC/MT1696/015

This talk is devoted to the fast solution of interface-concentrated finite-element equations. The interface concentrated finite element schemes are constructed on the basis of a non-overlapping domain decomposition where a conforming boundary concentrated finite element approximation is used in every subdomain. Similar to the boundary element domain decomposition method the total number of unknowns per subdomain behaves like $O((H/h)^{(d-1)})$, where H, h, and d denote the usual scaling parameter of the subdomains, the average discretization parameter of the subdomain boundaries, and the spatial dimension, respectively. We propose and analyze primal and dual substructuring iterative methods which asymptotically exhibit the same or at least almost the same complexity as the number of unknowns. In particular, the so-called All-Floating Finite Element Tearing and Interconnecting solvers are highly parallel and very robust with respect to large coefficient jumps.

New asymptotic estimates for spherical designs. **Andriy Bondarenko** (Kyiv University, Ukraine), Maryna Viazovska (TU Kaiserslautern, Germany) IC/CT1308/022

Let S^n be the unit sphere in $\mathbb{R}^{n+1}$. The set of vectors $\vec{x}_1, \dots, \vec{x}_N \in S^n$ is called a *spherical t-design* if

$$\frac{1}{mes\, S^n} \int_{S^n} p(\vec{x})\, \mathrm{d}\vec{x} = \frac{1}{N} \sum_{i=1}^{N} p(\vec{x}_i)$$

for all algebraic polynomials in $n+1$ variables and of degree at most t (see[1]). The low bound for cardinality $N = N(n,t)$ of spherical t-designs

$$\begin{cases} N(n,t) \geq \binom{n+k}{n} + \binom{n+k-1}{n} & \text{for } t = 2k, \\ N(n,t) \geq 2\binom{n+k}{n}, & \text{for } t = 2k+1, \end{cases}$$

is also proved in [1], that implies $N(n,t) \geq c(n)t^n$. It is also known [2] that $N(n,t) < +\infty$ for each n and t. For each fixed $n \in \mathbb{N}$ the upper bounds $N(n,t) \leq C(n)t^{\alpha_n}$, $t \to +\infty$, where $\alpha_n = O(n^4)$, $\alpha_n = O(n^3)$, $\alpha_n = (n^2+n)/2$ are proved in [3], [4] and [5] respectively. Our main result is as follows.

Theorem *Let a_n be the sequence defined by*

$$a_1 = 1, \quad a_{2n} = a_{2n-1} + 2n, \quad a_{2n-1} = 2a_{n-1} + n, \quad n \in \mathbb{N}.$$

Then, for all $n,t \in \mathbb{N}$ we have $N(n,t) \leq C(n)t^{a_n}$, where $C(n)$ is a constant depending only on n.

Corollary *For all $n,t \in \mathbb{N}$ with $n \neq 1$, we have $N(n,t) \leq C(n)t^{\frac{3}{2}n\log_2 n}$.*

On Wachspress pentagonal patches. **Aparajita Ojha** (IIIT Jabalpur, India) IC/CT3445/015

Wachspress initiated the study of rational basis functions for finite element which have emerged as interesting tools for surface generation with desired smoothness over a region which accept partition in to polygonal or curved elements. He has mainly studied the constructional aspects of rational basis function for functional approximation. Later Gout and other mathematicians studied the interpolatory and convergence properties of lower degree rational finite element and their application in solving second order boundary value problems. These functions exhibit elegant mathematical properties. Due to their mathematical properties Dahmen, Dikshit and Ojha (Computer Aided Geometric Design, 17(2000), 879-890.) studied Wachspress quadrilateral patches from CAGD point of view. In (H.P. Dikshit and A. Ojha, Computer Aided Geometric Design, 19(2002), 207-224) conditions under which a composite quadrilateral patch will be C^1 continuous, has been studied. Further a simple subdivision formula has also been obtained in (H.P. Dikshit and A. Ojha, Computer Aided Geometric Design, 20(2003), 395-399)In this talk we shall present the construction of a pentagonal Wachspress type quadratic rational finite element patches. Among other things we shall present a nonnegative basis for the surface modeling over pentagonal partitions. Further, we shall discuss their interpolatory properties for construction of boundary elements interpolation. We shall conclude by giving the conditions under which a composite Wachspress patch will be C^1. A few example composite surfaces will be demonstrated fro possible applications in Computer Aided Geometric Design and Geometric Modelling applications.

Connectedness of number theoretic tilings. **Nertila Gjini** (University of New York, Tirana, Albania) IC/CT632/015

A non-empty set in $\mathbb{R}^n$ is called a *tile* if it coincides with the closure of its interior. If a finite set of tiles and their translations covers the space $\mathbb{R}^n$ without overlapping, then we say it forms a *tiling*. We study the connectedness of Pisot dual tilings which play an important role in the study of β-expansion, substitution and symbolic dynamical system. It is shown that each tile generated by a Pisot unit of degree 3 is arcwise connected. This is naturally expected since the digit set consists of consecutive integers. However surprisingly, we found families of disconnected Pisot dual tiles of degree 4. We proved that each tile of a tiling is connected or disconnected having infinitely many components. Also we give a simple necessary and sufficient condition for the connectedness of the Pisot dual tiles of degree 4. As a byproduct, a complete classification of the β-expansion of 1 for quartic Pisot units is given.

A strategy for parallel implementation of finite-difference schemes associated to evolution PDEs. **Carlos deMoura** (UERJ, Brazil), Maria Clícia Stelling deCastro (Universidade do Estado do Rio de Janeiro, Brazil), Vinícius Buçard deCastro (Universidade do Estado do Rio de Janeiro, Brazil) IC/CT2735/012

In the framework of parallel numerical treatment of PDEs, stationary (or time-frozen) equations have much more results available than the evolution (or time dependent) ones. This is justified as computer simulation of time flow, an intrinsically sequential phenomenum, leads naturally to a sequential algorithm, thus inhibiting any concurrency search. Among different approaches to circumvent this deadlock, the ones by Douglas *et al.* (frequency domain) and J.-L. Lions *et al.* (iterations), cf. [1,2], are worth mentioning.

The time-stepping strategy for PDEs is based on the fundamental semi-group property, sequentially read as:

$$u(t+\tau) = S(t)\big[S(\tau)\,u(0)\big]\,,$$

while its parallel view looks as

$$u(t+\tau) = \big[S(t)\,S(\tau)\big]\,u(0)\,,$$

which, for $t_n := n\Delta t$, gives

$$u(N\Delta t) = \big[S(t_{N-1})\,S(t_{N-2})\,\ldots\,S(t_0)\big]\,u(0)\,.$$

While looking at finite-difference schemes (FDS), replacement of the sequential view by the parallel one is equivalent to exchanging matrix–vector and matrix–matrix multiplications. But these latter can be carried out in parallel for linear problems. For any explicit FDS, this strategy, herein proposed and called *matrix-multiply method* (M^3), presents a speed-up of order $(2\ell\log_2 P)/P$ for P^2 active processors and ℓ the associated matrix half-band.

We emphasize:

- M^3 preserves all FDS stability and accuracy properties;
- all (space or time) mesh adaptive procedures may be kept along;
- speed-up estimate holds despite the filling caused by multiplications;
- Strassen-like product schemes lead to computer time improvement.

Experimental results are being conducted throughout different platforms. We should recall that part of this strategy was mentioned (for ODEs) almost 20 years ago by D.J. Evans, cf.[3].

Finite-element approximation to the equation of motion arising in Oldroyd model. **Amiya Pani** (IIT Bombay, India) IC/CT2907/025

Newton's model of incompressible viscous fluid is described by the wellknown Navier–Stokes equations. This has been a basic model for describing flow at moderate velocities of majority of viscous incompressible fluids encountered in practice. However, models of viscoelastic fluids have been proposed in the mid twentieth century which take into consideration the prehistory of the flow and are not subject to Newtonian flow. One such model was proposed by J.G. Oldroyd and hence, it is named after him. The equation of motion in this case gives rise to the following integro-differential equation

$$\frac{\partial u}{\partial t} + u\cdot\nabla u - \mu\Delta u - \int_0^t \beta(t-\tau)\Delta u(x,\tau)\mathrm{d}\tau + \nabla p = f(x,t)\,,\ x\in\Omega, t>0\,,$$

and incompressibility condition

$$\nabla \cdot u = 0\,,\ \ x \in \Omega, t > 0\,,$$

with initial condition

$$u(x,0) = u_0, u = 0,\ x \in \partial\Omega, t \geq 0\,.$$

Here, Ω is a bounded domain in $\mathbb{R}^d$ $(d = 2,3)$ with boundary $\partial\Omega$, $\mu > 0$ and the kernel $\beta(t) = \gamma exp(-\delta t)$, where both γ and δ are positive constants.

With a brief discussion on existential analysis, in this talk we concentrate on the finite element Galerkin method for the above system under realistically assumed regularity on the exact solutions. Since the problem is an integral perturbation of the Navier–Stokes equations, we would like to discuss *how far the results on finite element analysis for the Navier–Stokes equations can be carried over to the present case.*

Umbrella based triangulation of regular parametric surfaces. **Victoria Hernández Mederos** (ICIMAF, Havana, Cuba) IC/CT5068/020

IC/CTS4610/02: Factorizations and splittings.

Organiser: Martin Gutknecht (ETH Zürich, Switzerland)

Sparse direct factorizations based on unassembled hyper-matrices. **Paolo Bientinesi** (Duke University, USA), Victor Eijkhout (University of Texas at Austin, USA), Jason Kurtz (University of Texas at Austin, USA), Robert van de Geijn (University of Texas at Austin, USA) IC/CT252/020

This work is motivated by the observation that, for highly dynamic applications, traditional sparse direct solvers address the wrong problem. Such methods have focused on the efficient solution of an individual linear system, stored as a matrix in any traditional format, by manipulating the connectivity graph of the discretized domain and ordering degrees of freedom optimally.

In the setting of a FEM application with local mesh refinement and unrefinement, a factorization of a given linear system may already exist. It is the *updated* linear system of the (un)refined mesh for which a factorization must be computed in the least amount of time. That is, only parts of the matrix affected by refinement and/or unrefinement need to be updated. This observation holds the promise of a tremendous reduction in the cost of an individual refinement step.

We argue that traditional matrix storage schemes, whether dense or sparse, are a bottleneck, limiting the potential efficiency of the solvers. We propose a new data structure, the *Unassembled Hyper-Matrix* (UHM), which preserves useful information that can be provided by the application, and that can make the solver, as well as various other operations on the matrix, more efficient. In particular, this can be used to implement an efficient sparse direct solver for hp adaptive finite element problems.

On Hermitian and skew-Hermitian splitting iteration methods. **Zhong-Zhi Bai** (Chinese Academy of Sciences), Gene Golub (Stanford University, USA), Chi-Kwong Li (College of William and Mary, USA) IC/CT2784/020

The Hermitian and skew-Hermitian splitting (HSS) iteration scheme is an efficient and practical method for solving large sparse non-Hermitian system of linear equations. In this talk, after reviewing the HSS iteration method and its basic convergence theory for non-Hermitian positive definite matrices, we give a sufficient and necessary condition for guaranteeing its convergence for nonsingular and non-Hermitian positive semidefinite matrices. We then discuss the semi-convergence property of the HSS iteration method and derive a sufficient and necessary convergence condition for singular and non-Hermitian positive semidefinite matrices.

According to the optimal iteration parameter involved, we first compute it exactly for real two-by-two matrices, and then compute it exactly for special block two-by-two matrices. These formulas are used to give estimation for the optimal iteration parameter of HSS iteration method for general non-Hermitian matrices. Finally, some numerical results are used to examine the effectiveness of the HSS iteration method with the exact or the estimated optimal iteration parameter.

This talk includes works jointly finished with Prof. Gene H. Golub and Prof. Chi-Kwong Li.

Application of operator splitting in the solution of reaction–diffusion equations. **Tamas Ladics** (Budapest University of Technology and Economics, Hungary) IC/CT3117/015

Operator splitting is a widely used method in the numerical solution of partial differential equations (see: Marchuk, G.I., 1968: Some application of splitting-up methods to the solution of mathematical physics problems. *Applik. Mat.*, 13.). It has fruitful applications in for modeling of air pollution transport or in the solution of reaction-diffusion problems (see: Tamas Ladics, 2005: The analysis of the splitting error for advection-reaction problems in air pollution models. *Idojaras, Quarterly Journal of the Hungarian Meteorological Service*, Vol.109, No. 3, pp.173–188).

Operator splitting by its nature is convenient to implement on parallel computers. A comparison of the different splitting techniques in the solution of 1 and 2 dimensional reaction-diffusion equations is made. The process of the solution is a composition of certain splitting procedure and a given numerical method. We study the interaction between the different splitting procedures and different numerical schemes. The order of the convergence of this composed method is calculated. The error of the approximate solution is characterized as a function of the applied splitting and numerical scheme.

Pseudo-spectral finite-difference method for solving a 3D dual-phase-lagging heat-transport equation in a microscale thin film. **Sayed Hodjatollah Momeni-Masuleh** (Shahed University, Iran) IC/CT797/015

Non-Fourier microscale effects are significant during the rapid heating of metallic substrates. The heat transport equation is different from the traditional heat diffusion equation since a second-order derivative of temperature with respect to time and a third-order mixed derivative of temperature with respect to space and time are introduced. This study aims to develop a time dependent pseudospectral-finite difference scheme for solving a 3D dual-phase-lagging heat transport equation in a microscale thin film. The scheme uses periodic pseudospectral discretization in space and a fully second-order finite difference discretization in time. The scheme is illustrated by numerical examples. Comparisons are made with available literature.

Practical Newton-like acceleration algorithms for nonlinear system at singular roots. **Zorana Lužanin** (University of Novi Sad, Yugoslavia), Nataša Krejić (University of Novi Sad, Yugoslavia) IC/CT826/015

A new modification of Broyden, discrete Newton, column-updating and Thomas methods for solving singular system of nonlinear equations is introduced. Quasi-Newton methods are slower (linear or sublinear), if the Jacobian is singular at the solution. With the new modification convergence becomes linear or superlinear. The theory and method are illustrated by several examples.

IC/CTS4630/02: Numerical methods for differential equations.

Numerical consistency of high-order Galerkin-type polynomial methods for the reduction of round-off errors. **Jae-Hun Jung** (Univ. Massachusetts at Dartmouth, USA), Sigal Gottlieb (Univ. Massachusetts at Dartmouth, USA) IC/CT3060/025

Multi-domain penalty Galerkin polynomial spectral methods are well known to yield increasing order of accuracy for the smooth problems as the polynomial order is increased. Depending on the form of the penalty-type interface/boundary conditions there may exists a certain order of polynomial beyond which the spectral accuracy is no longer maintained but the round-off errors become dominant.

In this talk, we derive the general weak formulation using penalty-type interface/boundary conditions in multi-domain penalty Galerkin spectral method. We show that depending on the particular form of the penalty term, the derived multi-domain penalty Galerkin spectral method can be made equivalent to the discontinuoud Galerkin method. Our numerical results demonstrate that for some choices of penalty terms, an inconsistency in the techniques for evaluating the integrals may result in increased sensitivity to round-off errors, whereas consistent evaluations of the mass and the load vector produce more accurate results.

We also present a technique for reducing the sensitivity of round-off errors for high order polynomial Galerkin methods by exploiting their spectral convergence property. The expansion coefficients of the smooth solution obtained by the these methods decays exponentially. This decay rate deteriorates when the round-off errors become dominant. By truncating them properly, in a way which mimics spectral decay, we resolve the "exponential" error growth for high order polynomials. Some numerical experiments will be presented to show the high accuracy of the proposed method.

Miminal stabilization of discontinuous Galerkin finite-element methods for hyperbolic problems. **Benjamin Stamm** (École Polytechnique Fédérale de Lausanne, Switzerland), Erik Burman (École Polytechnique Fédérale de Lausanne, Switzerland) IC/CT1947/026

We consider a discontinuous Galerkin finite element method for the advection–reaction equation in two space–dimensions. For polynomial approximation spaces of degree greater than or equal to two on triangles we propose a method where stability is obtained by a penalization of only the upper portion of the polynomial spectrum of the jump of the solution over element edges. We prove stability in the standard h-weighted graph-norm and obtain optimal order error estimates with respect to mesh-size.

An application of some high-order operator-splitting methods to systems of stiff differential equations. **Francisco Sánchez-Bernabe** (Universidad Autonoma Metropolitana Iztapalapa, Mexico), Javier Salcedo-Ruiz (Instituto Politecnico Nacional, Mexico) IC/CT2589/025

In this work we compare operator splitting methods of high order that are applied to systems of stiff diffusion equations. In order to efficiently solve the resultant subproblems of these decomposition techniques is necessary to use implicit Runge-Kutta methods. Some operator splitting schemes were generated by applying Richardson extrapolation to lower order decomposition methods. It is known that, in this context, the accuracy of operator splitting schemes is reduced. However, we have observed that the order reduction is not very severe for high order operator splitting methods.

Numerical dissipativity of multistep methods for delay-differential equations. **Hongjiong Tian** (Shanghai Normal University, PR China) IC/CT1126/024

Dissipative differential equations have frequently appeared in the fields of physics, engineering, and biology. In this paper we investigate numerical dissipativity of linear multistep and one-leg methods applied to a class of dissipative delay differential equations. We show that for such class of dissipative systems these numerical methods are dissipative if and only if they are $A-$stable for ordinary differential equations. One numerical experiment is given to illustrate our result.

Long-memory Mori–Zwanzig models for the Euler equations. **Panagiotis Stinis** (Lawrence Berkeley National Laboratory, USA) IC/CT3020/025

A long memory model for dimensional reduction, known as the t-model, is derived through the Mori–Zwanzig formalism of irreversible statistical mechanics. The model is applied to the estimation of the rate of decay of solutions of the Burgers equation and of the Euler equations in two and three space dimensions. In the Burgers case, the model captures the rate of decay exactly. For the Euler equations in two space dimensions, the model preserves energy as it should. In three dimensions, we find a power-law decay in time and observe a temporal intermittency. The t-model is the first in a hierarchy of Mori–Zwanzig models.

This is joint work with A. Chorin, O. Hald and Y. Shvets.

Highly-efficient compact finite-difference methods for nonlinear partial differential equations. **Jichao Zhao** (INRIA, France) IC/CT2681/027

Multigrid method (MG) has been widely accepted as an efficient approach for solving linear elliptic partial differential equations. The multigrid method when combined with nested iteration, called Full Multigrid method (FMG), can solve linear matrix equations to the accuracy of the truncation error in a number of operations that is proportional to the number of unknowns. This powerful solver has a two-grid process, the fine-grid smooth and coarse-grid correction. To solve nonlinear partial differential equations, there are two basic approaches, Newton method and Full Approximation Scheme (FAS), to combine with the multigrid method, as demonstrated in Henson's overview (2000). Using higher order approximations in the fine-grid smooth or coarse-grid correction or both processes of the multigrid method provides a means of obtaining the same accuracy with much less computational time and amounts of storage compared with the common used second-order finite difference scheme. Schaffer (1985) and Burger and Fulton (1999) compared the three higher-order multigrid methods to solve linear elliptic partial differential equations: (i) smoothing with higher-order difference scheme via compact finite differ-

ence schemes (Mehrstellen Verfahren discretizations), (ii) iterated defect corrections with multigrid method used as an inner loop solver, and (iii) tau extrapolation, and they all concluded that the compact finite difference method is the most accurate and efficient one among these discretizations considered in their work.

In our work, we give the fourth-order compact finite difference scheme, combined with the FAS and Newton's method respectively, to solve nonlinear elliptic partial differential equations. We compare numerical results obtained by the compact finite difference method with the widely used second-order finite difference method, and the another higher-order method – iterated defect corrections, and draw the conclusion that the compact finite difference method combined with the multigrid method is a very efficient and accurate scheme for nonlinear elliptic partial differential equations. However, we must admit that it is quite complicated to generate compact finite difference schemes by hand, especially for general nonlinear partial differential equations or high dimensional problems, considering these higher-order schemes involve more grid points. To make life easier, we make a Maple package "CompactScheme" to generate these higher-order compact finite difference schemes for very general partial differential equations so that users can easily use them for their own purposes.

This is a join work with Dr. Jean-Antoine Désidéri and Alex Potapchik.

IC/CTS4603/02: Interpolation, quadrature, ODEs and integral equations.

Organiser: Leonid Knizhnerman (Central Geophysical Expedition, Russian Federation)
Co-organiser: Michael Minion (University of North Carolina, USA)

Choice of frequency interpolation nodes for solving a multi-frequency problem with a nonnegative definite operator. **Leonid Knizhnerman** (Central Geophysical Expedition, Russian Federation), Vladimir Druskin (Schlumberger Ltd., USA), Mikhail Zaslavsky (Schlumberger Ltd., USA) IC/CT2203/024

Let us have a family of equations:

$$(A + i\omega)u_\omega = \varphi, \qquad 0 < \omega_{\min} \le \omega \le \omega_{\max},$$

where A is a self-adjoint non-negative definite operator in a Hilbert space and φ is a nonzero vector. Given n, we wish to find basic frequencies ω_j, $1 \le j \le n$, such that u_ω can be well approximated by linear combinations of u_{ω_j}.

We have experimentally found out that good enough basic frequencies can be extracted from Zolotaryov's approximation to $\omega^{-1/2}$ on a bounded positive interval. The coefficients x_j of linear combinations can be obtained via solution of Galerkin type systems in the weighted spectral functional space:

$$(\lambda + i\omega)\sum_{j=1}^{n} x_j \frac{1}{\lambda + i\omega_j} - 1 \perp \frac{1}{\lambda + i\omega_k}, \qquad 1 \le k \le n.$$

Here $\lambda \ge 0$ represents the spectrum of A and the weight function is $\lambda^{-1/2}$.

The use of the real and imaginary parts of $\frac{1}{\lambda+i\omega_k}$ makes the convergence twice faster.

A hypothesis on the approximation error has been formulated. It is illustrated with the results of numerical experiments.

Accelerating the convergence of spectral deferred-correction methods for stiff ODEs and DAEs. **Michael Minion** (University of North Carolina, USA), Anita Layton (Duke University, USA), Jingfang Huang (University of North Carolina, USA), Jun Jia (University of North Carolina, USA) IC/CT4466/024

Spectral deferred correction methods (SDC) for ODEs have been shown to possess favorable accuracy and stability properties even for versions with very high order of accuracy. Unfortunately, for very stiff problems, SDC methods exhibit order reduction for a range of time-step values. I will show that for linear problems, the iterations in the SDC algorithm are equivalent to constructing a preconditioned Neumann series expansion for the solution of the standard collocation discretization of the ODE. I will explain the connection between order reduction and the convergence of this series. These observations motivate the use of Krylov subspace methods to accelerate the convergence of SDC for both ODEs and DAEs. The resulting methods possess increased stability and efficiency compared to the original SDC approach, and the acceleration effectively eliminates order reduction in the preliminary linear and nonlinear numerical experiments studied thus far.

Complexity of initial-value problems for ordinary differential equations of order-k. **Marek Szczęsny** (Akademia Górniczo-Hutnicza, Poland) IC/CT4083/015

We present results on the solution of initial-value problems for ordinary differential of order k. Our aim is to compute an ε-approximation to the solution. We study the dependence of the minimal error on the order k of the equation. We assume that the right-hand side function has r continuous bounded partial derivatives. We consider three models of computation: deterministic, randomized and quantum.

In the deterministic case we consider two types of information: standard information and linear one. For standard information, we show that the worst-case ε-complexity is $\Theta((1/\varepsilon)^{1/r})$, which is independent of k. Linear information is more powerful. We show that the ε-complexity in a class of equations is $\Theta((1/\varepsilon)^{1/(r+k)})$.

We also study possible advantages of randomized and quantum computing over deterministic computing. We show that a speed-up dependent on k is not possible in the randomized and quantum settings. We establish lower complexity bounds, showing that the randomized and quantum complexities are $\Theta((1/\varepsilon)^{1/(r+1/2)})$ in the randomized setting and $\Theta((1/\varepsilon)^{1/(r+1)})$ in the quantum setting. That is, they remain at the some level as for systems of the first order, no matter how large k is.

Numerical methods for surface diffusion on elastically stressed solid surface. **Xiaofan Li** (Illinois Institute of Technology, USA) IC/CT4331/023

The surface diffusion of an axisymmetric solid, a whisker, subject to applied uniaxial stress, is studied numerically based on a new boundary integral formulation for periodic stress configurations. Efficient and accurate numerical methods for solving the boundary integral equation for elasticity and the severely stiff differential equations are presented. Numerical simulations of a fully nonlinear case are also presented, and evidences of singularity formation of the whisker are shown.

Numerical solution of integral equations using Legendre-wavelet functions. **Sohrab Rahbar** (Iran Research Organization of Science/Technology) IC/CT4974/023

Two methods for solving the linear and non-linear Fredholm integral equation of the second kind; i.e.,

$$f(x)-\lambda\int_a^b K(x,y)f(y)dy=g(x),\quad f(x)-\lambda\int_a^b K(x,y)F(f(y))dy=g(x),$$

are proposed. In order to solve the linear equation, the kernel $K(x,y)$ as well as the functions f and g are initially approximated through Legendre-wavelet functions. This leads to a system of linear equations whose solution provides a solution to the linear Fredholm integral equation.

In the second method for non-linear case, only the kernel $K(x,y)$ is approximated by Legendre-wavelet base functions. This leads to a separable kernel and makes it possible to employ a number of earlier methods in solving non-linear Fredholm integral equation with separable kernels. Another feature of the proposed method is that it finds the solution as a function instead of specific solution points, what is done by the majority of the existing methods.

A quadrature free convergent method for the numerical solution of linear Fredholm integral equations based on Hermit-spline interpolation. **Sedghat Shahmorad** (University of Tabriz, Iran) IC/CT603/023

In this paper we use the Hermite-spline interpolation in a special form for the numerical solution of linear Fredholm integral equations. We prove the convergence of this method as a main part of the paper and give an error bound for the error controlling of numerical results. Finally some numerical results are given to certify convergence and error bound of the method.

IC/CTS4926/02: Numerical linear algebra.

Organiser: Jan Mayer (Universität Karlsruhe, Germany)
Co-organiser: Martin Gutknecht (ETH Zürich, Switzerland)

ILU++: a new software package for solving sparse linear systems with iterative methods. **Jan Mayer** (Universität Karlsruhe, Germany) IC/CT1191/002

ILU++ is a new software package using a multilevel incomplete LU-factorization as a preconditioner. For better stability and sparsity, the factorization implements either pivoting by both rows and columns and/or sophisticated preordering and scaling techniques. Some of these techniques come from existing software packages (PARDISO, METIS), while others are new. ILU++ is written in C++ and fully templated, allowing for great flexibility. In particular, it can be easily integrated as a solver in other software.

A parallel Krylov–Schur implementation for large Hermitian and non-Hermitian eigenproblems. **Andrés Tomás** (Universidad Politecnica de Valencia, Spain), Vicente Hernández (Universidad Politecnica de Valencia, Spain), José Román (Universidad Politecnica de Valencia, Spain) IC/CT1524/012

Sorensen's implicitly restarted Arnoldi (IRA) algorithm is one of the most successful methods for finding a few eigenpairs of a large sparse matrix. The Krylov–Schur algorithm has been recently proposed by Stewart as an interesting alternative with two advantages over IRA. The first one is the ease of deflation of converged Ritz vectors, and the second one is the avoidance of the potential forward instability of the QR algorithm.

This work presents a new implementation of a Krylov–Schur eigensolver in SLEPc (Scalable Library for Eigenvalue Problem Computations), a software library for the solution of large, sparse eigenvalue problems on parallel computers. SLEPc can be used for the solution of problems formulated in either standard or generalized form, both Hermitian and non-Hermitian, with either real or complex arithmetic. It is built on top of PETSc (Portable, Extensible Toolkit for Scientific Computation) a parallel framework for the numerical solution of partial differential equations.

This Krylov–Schur implementation pursues numerical stability as well as parallel efficiency. The numerical stability of the implementation is assessed by an empirical test with a battery of about 200 public domain real-problem matrices.

The parallel performance analysis has been performed in a cluster platform with 55 nodes, computing a few extreme eigenpairs of large Hermitian and non-Hermitian problems. In particular, it has been compared with the IRA implementation from the ARPACK library and with the Arnoldi method with explicit restart from SLEPc. In addition, for Hermitian problems, it has been compared with several Lanczos variants with explicit restart from SLEPc.

Although the speed-up of this Krylov–Schur implementation is as good as the compared methods, the elapsed sequential time is lower, resulting in better overall performance.

Computing transfer function dominant poles of large-scale second-order dynamical systems. **Joost Rommes** (NXP Semiconductors, The Netherlands) IC/CT4569/020

A new algorithm for the computation of dominant poles of transfer functions of large-scale second-order dynamical systems is presented: Quadratic Dominant Pole Algorithm (QDPA). The algorithm works directly with the system matrices of the original system, so no linearization of the corresponding quadratic eigenvalue problem is needed. To improve global convergence, QDPA uses subspace acceleration, and deflation of found dominant poles is implemented in a very efficient way. The dominant poles and corresponding eigenvectors can be used to construct structure-preserving modal approximations, but also to improve reduced-order models computed by rational Krylov subspace methods, as is illustrated by numerical results. Generalizations to MIMO systems, higher-order systems and the computation of dominant zeros are also discussed.

Behaviour of the simple genetic algorithm. **Stefan Kotowski** (Polish Academy of Sciences, Poland) IC/CT4789/012

There will be presented the possibility of generating the limit distribiution of the simple genetic algorithms in optimal way, (possibly in one step). The formal construction of the best genetic algorithm as the idea for construction real genetic algorithm as the approximation the possibly best genetic algorithm will be presented.

A comparison between different bases in image reconstruction from non-uniform samples. **Reginaldo Santos** (Universidade Federal de Minas Gerais, Brazil) IC/CT2248/021

We present two methods based on the application of Conjugate Gradient method that use wavelets and shift invariant spaces bases. We give an efficient way of computing the products Ax and A^*y for each basis. We compare, experimentally, our approach for image reconstruction from nonuniform samples when using Fourier, D6 wavelets and uniform cubic splines bases.

Finite volume-element method for miscible displacement problem in porous media. **Sarvesh Kumar** (IIT Bombay, India) IC/CT2884/025

We present the finite volume element methods (FVEM) for incompressible miscible displacement problems in porous media. The miscible displacement in porous media is modeled by a nonlinear system of two partial differential equations, one is pressure equation and other is called concentration equation. For the approximation of pressure equation we use mixed FVEM and for approximating the concentration equation we apply the standard FVEM. Optimal error estimates are derived for velocity as well as concentration. Numerical results confirm the theoretical order of convergence.

Diaphonies on Sobolev classes of functions. **Raffaello Seri** (Università degli Studi dell'Insubria Varese, Italy) IC/CT4362/002

The aim of this paper is to provide a general way to build Koksma–Hlawka inequalities for integration of Sobolev functions through a sample of monte Carlo and quasi-Monte Carlo points. The technique is very general and can be applied, as an example, to the hypercube, the hypersphere and the disc. The bound in the inequality is given by the product of a term depending only on the function to be integrated (and on a pseudodifferential operator) and a term depending on the sample of points and given by a diaphony in the sense of Amstler and Zinterhof. It is also possible to give a general interpretation of these diaphonies as worst-case integration errors of quadrature rules. A consequence is that Giné Sobolev tests used in Statistics coincide with diaphonies appearing in Koksma-Hlawka inequalities based on pseudodifferential operators in the spirit of Cui and Freeden for the integration of Sobolev functions defined on compact Riemannian manifolds.

Work done in collaboration with Christine Choirat.

Weighted moving finite elements applied to reacting and non-reacting flow problems, including applications with remeshing and refining. **Abigail Wacher** (Finavera Renewables Ltd., Canada), Dan Givoli (Technion-Israel Institute of Technology) IC/CT932/002

Solving problems containing complex structures or moving shocks using standard methods can be computationally expensive, and using an adaptive mesh to *track* moving fronts and boundaries has been shown to provide cheaper and more accurate computations, making them a good candidate for solving large-scale problems in several areas in the Engineering Sciences.

Recently my work has focused on the development and implementation of a moving mesh technique called *String Gradient Weighted Moving Finite Elements* (suggested by K. Miller in 1997). I will introduce the method and present results to several systems of nonlinear partial differential equations, including a two dimensional model of a chemical reaction, the porous medium equation, and solutions to the dispersive and non-dispersive nonlinear shallow water equations.

Two deficiencies of the original SGWMFE method are (1) possible tangling of the mesh which causes the method's failure, and (2) no mechanism for global refinement when necessary due to the constant number of degrees of freedom. Recently the method has been extended in order to continue computing solutions when the meshes become too distorted, which happens quickly when the flow is rotationally dominant. Optimal rates of convergence are obtained when remeshing is applied. The method is also extended to include refinement to enable handling of new physical phenomena of a smaller scale which may appear during the solution process. It is shown that the errors in time are kept under control when refinement is necessary. Results of the extended method for some example problems of water hump release are presented.

Numerical solution of the dynamic problem of the elasticity theory in arbitrary shaped plane domain. **Galina Ribacova** (Moldova State University) IC/CT942/027

The large number of problems connected with numerical modeling of different physical processes leads to necessity of creation of effective methods of discretization of the computational fields with complicated shape. In order to solve this problem there are often used the methods based on application of the elliptical type partial differential equations for description of the interconnection between the computational (ξ, η) and physical (x, y) regions [1]. In present article the method of creating the regular two dimensional curvilinear grids based on the solution of the problem of longitudinal elastic plate deformation is presented. Mathematically the problem represents the system of partial differential equations of elliptic type – Lame's equations [2]. To formulate the problem let us consider the rectangular elastic plate. Let the rectangular uniform grid with the grid points $\left(x_i, y_j\right), x_i = ih_x, y_j = jh_y, i = \overline{0,n}, j = \overline{0,m}$, ($h_x = l_1/n, h_y = l_2/m$ – the steps of the grid on corresponding variable, l_1 and l_2 – the dimensions of rectangular plate) is marked on this plate. If now the plate is exposed to longitudinal deformation so as its boundaries take some given form (the form of boundaries of the region where the grid must be constructed), then the grid, which was marked on plate, will be deformed too. As a result of such deformation we obtain the unknown grid. The problem is solved numerically by means of finite difference method with second order accuracy on the rectangular grid that has been introduced above [3]. The developed algorithm was applied for discretization of the regions with complicated geometrical structures.

The finite-element method for a class of degenerate elliptic equations. **Hengguang Li** (Department of Mathematics, the Pennsylvania State, USA) IC/CT736/026

Consider the degenerate elliptic operator $\mathcal{L}_\delta := -\partial_x^2 - \frac{\delta^2}{x^2}\partial_y^2$ on $\Omega := (0,1) \times (0,l)$, for $\delta > 0, l > 0$. We prove well-posedness and regularity results for the degenerate elliptic equation $\mathcal{L}_\delta u = f$ in Ω, $u|_{\partial\Omega} = 0$ using weighted Sobolev spaces K_a^m. In particular, by a proper choice of the parameters in the weighted Sobolev spaces K_a^m, we establish the existence and uniqueness of the solution. In addition, we show that there is no loss of K_a^m-regularity for the solution of the equation. We then provide an explicit construction of a sequence of finite dimensional subspaces V_n for the finite element method, such that the optimal convergence rate is attained for $u_n \in V_n$, i.e., $||u - u_n||_{H^1(\Omega)} \leq C\dim(V_n)^{-\frac{m}{2}}||f||_{H^{m-1}(\Omega)}$ with C independent of f and n. Numerical results will be shown.

Mixed spectral method for 3D exterior problems using spherical-harmonic and generalized-Laguerre functions. **Zhongqing Wang** (Shanghai Normal University, PR China) IC/CT1528/014

In this talk, we develop the mixed spectral method for three-dimensional exterior problems, using spherical harmonic and generalized Laguerre functions. Some basic approximation results are established. The mixed spectral schemes are proposed for two model problems. Their convergences are proved. Numerical results demonstrate the efficiency of this new approach.

Optimized Schwarz methods for the spherical Laplacian with corners. **Sébastien Loisel** (Temple University, USA) IC/CT4513/027

Numerically solving the Laplace problem on the sphere is important in several fields, including meteorology. When the number of grid points is large, one possibility to solve the linear problem $Lu = f$ is to use an iterative method. One such method is the Schwarz iteration. Several difficulties are particular to the sphere. First, the spherical Laplacian is singular, so the Schwarz iteration does not converge in the traditional sense. Second, Optimized Schwarz Methods (OSM) (which replace the Dirichlet problem by a Robin or higher order problem) have difficulties dealing with corners and multiple intersections of subdomains. Third, coarse grid corrections are not well understood for OSM. Fourth, convergence results for OSM are not generally known for optimized parameter values. In this talk, we will address all of these issues.

Adaptive finite-element meshing scheme for the steady Navier–Stokes equations. **Hyung-Chun Lee** (Ajou University, Republic of Korea), Lili Ju (University of South Carolina, USA) IC/CT1886/027

A triangle mesh adaptivity algorithm for Navier–Stokes equations that combines *a posteriori* error estimate with centroidal Vorioni/Delaunay tessellations of domains in two demensions is proposed and tested. With *a posteriori* error estimate, mesh adaptativity algorithm has several desirable features. Errors are very well equidistibuted over the triangles. The achieved convergence rates are the best obtainable using Taylor-Hood finite elements.

Comparison of different methods applied to the solution of problems with non local boundary conditions. **Abdelaziz Chetouani** (Université Mohammed 1er Oujda, Morocco), Zakaria El Allali (Université Mohammed Premier Oujda, Morocco) IC/CT620/028

Non-linear equations with non-local boundary conditions are used to model several physical phenomena. An exhaustive description of the accuracy of such equations is given by Fairweather and Saylor. In this paper we give different methods for the numerical solutions of such equations. First, a family of numerical methods is developed for the numerical solution of a linear parabolic problem with boundary conditions containing integrals over the interior of the interval. The methods are seen to evolve from first- and second-order rational approximants to an exponential function in a recurrence relation. Global extrapolation procedures in space only and in both space and time are discussed. In the second part of this paper, we analyze a θ-method for the numerical solution of a semi linear parabolic problem with boundary conditions containing integrals over the interior of the interval, existence and convergence are proved for $\theta \leq \frac{1}{2}$; numerical application is given. in the last part of this paper a numerical comparison of the different methods is presented.

On the relation of topology and analysis in discrete mechanics. **Sigrid Leyendecker** (California Institute of Technology, USA), Michael Ortiz (California Institute of Technology, USA), Jerrold Marsden (California Institute of Technology, USA) IC/CT2076/028

Discrete mechanics can be understood as a discrete theory for the deformation of solids based on a discrete differential complex, thus the underlying (space-time)-domain is discrete *ab initio*. In contrast to the finite element approach, the emanating discretisation techniques are not based on the interpolation of nodal values where the appearing differential operators are applied to the interpolating shape functions, but the differential operators are discretised themselves and the corresponding discrete operators are applied directly to the nodal values. The resulting discrete problem is expressed in a manner formally identical to its continuous counterpart, exhibiting discrete analogues of whose properties.

Concepts of discrete calculus have been investigated in the context of vector field theories (see e.g. [1], [2]). However its extension to tensor field problems such as discrete elasticity is not straightforward. In particular for constrained problems, the design of stable approximation schemes with good convergence properties requires certain topological properties of the discrete domain as well as an analysis of the involved interpolation spaces, see [3]. The aim of the talk is to draw connections between the discrete topology and analysis in the regime of finite deformation of solids.

Regularization in dynamic SPECT. **Manfred Trummer** (Simon Fraser University, Canada) IC/CT4804/015

Single photon emission computed tomography (SPECT) is a widely used technique in diagnostic nuclear medicine. In the static setting, a constant image is assumed during the data acquisition process. In many applications, for example in the study of Teboroxime cardiac images, the activity varies with time. Reconstructing this time-dependent activity is the goal of dynamic SPECT. The problem is highly underdetermined, and thus ill-posed. A-priori information and regularization techniques must be used in the solution. We will present an algorithm for this problem based on Kalman filtering.

Acoustic scattering from multiple complexly-shaped obstacles. **Vianey Villamizar** (Brigham Young University, USA), Sebastian Acosta (Brigham Young University, USA) IC/CT4443/025

In this work, we develop an explicit finite-difference time-dependent method, based on boundary conforming coordinates including grid line control, to numerically solve two-dimensional scattering problems in the presence of multiple obstacles exhibiting boundary singularities. It constitutes an extension of previous work for single scatterers. The development of these methods requires appropriate definitions of radiation conditions at artificial infinite boundaries, the generation of curvilinear coordinates with efficient grid line control on multiply connected regions with several holes, and the reformulation of the boundary value problem (BVP) in terms of the new curvilinear coordinates. The scatterers are arbitrarily located inside the physical domain. The grid generation algorithm is capable of increasing the distance between grid lines in certain regions, where the Courant-Friedrichs-Lewy (CFL) stability condition may be violated. Hence, there is no need to further reduce the time step to reach stability as long as the size of each cell is maintained above the limits of stability. The computational advantage of the novel numerical method is revealed by applying it to various multiple scatterer configurations.

Spectral analysis of the discrete Helmholtz operator preconditioned with a shifted Laplacian. **Martin van Gijzen** (TU Delft, The Netherlands) IC/CT3501/020

Shifted Laplace preconditioners have attracted considerable attention as a technique to speed up convergence of iterative solution methods for the Helmholtz equation. We present a comprehensive spectral analysis of the Helmholtz operator preconditioned with a shifted Laplacian. Our analysis is valid under general conditions. The propagating medium can be heterogeneous, and the analysis also holds for different types of damping, including a radiation condition for the boundary of the computational domain. By combining the results of the spectral analysis of the preconditioned Helmholtz operator with an upper bound on the GMRES-residual norm we are able to provide an optimal value for the shift, and to explain the mesh-depency of the convergence of GMRES preconditioned with a shifted Laplacian. We will illustrate our results with a seismic test problem.

Comparison of algorithms for large scale nonlinear eigenvalue problems. **Yusaku Yamamoto** (Nagoya University, Japan) IC/CT2855/020

Given an $n \times n$ matrix $A(\lambda)$ whose elements depend on a scalar parameter λ, we consider a problem of finding the values of λ such that the linear equation $A(\lambda)\mathbf{x} = \mathbf{0}$ has a nonzero solution $\mathbf{x}$. We compare three algorithms. The first one is to apply Newton's method to nonlinear simultaneous equations consisting of $A(\lambda)\mathbf{x} = \mathbf{0}$ and some normalization constraint on $\mathbf{x}$. In the second approach, we view $A(\lambda)$ as a constant matrix and compute the eigenvalue of this matrix with the smallest modulus, which we denote by $e(\lambda)$. Then the value of λ that satisfies $e(\lambda) = 0$ is the solution of the original nonlinear eigenvalue problem. The third approach is similar to the second one, except that the smallest singular value of $A(\lambda)$ is used instead of the eigenvalue. Once the nonlinear eigenvalue λ is found, the eigenvector $\mathbf{x}$ can be computed from the null space of $A(\lambda)$.

We applied these methods to a nonlinear eigenvalue problem arising from theoretical fluid dynamics. In this problem, $A(\lambda)$ is a nonsymmetric matrix of order 35,000 to 100,000 and the smallest positive eigenvalue is sought. Numerical experiments show that it is difficult to obtain the desired eigenvalue with Newton's method unless a good approximation to the corresponding eigenvector $\mathbf{x}$ is available. In contrast, with the second and third approach we were able to compute the desired eigenvalue successfully. The third approach was more efficient since for a nonsymmetric matrix, the singular values can be computed more cheaply than the eigenvalues.

We also propose a method that can compute the nonlinear eigenvalues in a specified region of the complex plane using techniques from complex analysis.

A parallel eigenvalue-problem solver for computational nano-electronics. **Maxim Naumov** (Purdue University, USA), Ahmed Sameh (Purdue University, USA) IC/CT4100/020

Computational nanoelectronics gives rise to many large sparse eigenvalue problems. The energy levels of a nanodevice constitute important parameters that are needed to describe electronic transport. The energy levels can be found by solving a Hermitian eigenvalue problem, in which the eigenvalues of interest lie in an interior interval in the spectrum around 0.

In this talk we will present an approach that consists of using diferent mappings in combination with the Trace Minimization algorithm to obtain the desired eigenpairs. We will comment on its advantages compared to standard eigenvalue solvers/packages such as Lanczos and PARPACK. Finally, numerical experiments will also be presented.

Multi-level iterative solvers for the edge finite-element solution of the 3D Maxwell equation. **Mike Botchev** (Universiteit Twente, The Netherlands), Oleg Nechaev (Novosibirsk State Technical University, Russian Federation), Ella Shurina (Novosibirsk State Technical University, Russian Federation) IC/CT3115/002

In the edge vector finite element solution of the frequency-domain Maxwell equations, the presence of a large kernel of the discrete rotor operator is known to ruin convergence of standard iterative solvers. We extend the approach of [1] and, using domain decomposition ideas, construct a multilevel iterative solver where the projection with respect to the kernel is combined with the use of a hierarchical representation of the vector finite elements.

The new iterative scheme appears to be an efficient solver for the edge finite element solution of the frequency domain Maxwell equations. The solver can be seen as a variable preconditioner and, thus, accelerated by Krylov subspace techniques (e.g. GCR or FGMRES). We demonstrate the efficiency of our approach on a test problem with strong jumps in the conductivity.

An efficient numerical simulation method for railway vehicle-track dynamic interaction. **Akiyoshi Yoshimura** (Tokyo University of Technology, Japan) IC/CT2065/020

An efficient numerical simulation method for the railway vehicle-track dynamic interactions is described. Applying the finite element method for the rail modelled as an Euler beam, the following equations of motion are obtained.

$$M\ddot{\boldsymbol{u}} + C\dot{\boldsymbol{u}} + (K + K_t)\boldsymbol{u} = \boldsymbol{g}(t)$$

where $\boldsymbol{g}(t)$ contains the contact force between the wheel and the rail.

In the equation, the stiffness matrix can be expressed separately to the time-invariant term K and the time-dependent one K_t. Moreover, by investigating the linear algebraic structure of the model the time-dependent matrix K_t can be simply expressed as $K_t = \boldsymbol{a}_t\boldsymbol{a}_t^T$. The specially defined vector $\boldsymbol{a}_t$ has only a few nonzero elements. Applying the Newmark-β direct integration method for the numerical simulation, a linear system $A_t\boldsymbol{x}_t = \boldsymbol{b}_t$ is obtained. The A_t is a time-dependent, sparse symmetric positive definite matrix. The linear system has to be solved iteratively for each time step. Here A_t can be expressed as $A_t = A + \boldsymbol{a}_t\boldsymbol{a}_t^T$ and its time-dependent term $\boldsymbol{a}_t\boldsymbol{a}_t^T$ makes only a small change in the sparse matrix A_t. So the Sherman-Morrison formula can be used in the computation of the inverse A_t^{-1}, which enables a very efficient numerical simulation.

Spectra for infinite tridiagonal pseudo-Toeplitz matrices. **Winfried Grassmann** (University of Saskatchewan, Canada) IC/CT477/020

This talk deals with the eigenvalues and eigenvectors of a tridiagonal matrix A where the diagonally centred rows repeat after the first c rows. Let N be the dimension of A. It is shown that as $N \to \infty$, the set of eigenvalues becomes dense, except for up to a maximum of c isolated eigenvalues. We also show that the functions of A, such as e^A, can be expressed as the sum of an integral and terms deriving from the isolated eigenvalues. Numerical results for the case where all off-diagonal elements are positive are given, and they are encouraging. However, the number of points used to find the integral increases with the row number.

Application of a new generalized conjugate-direction method to the linear complementarity problem. **Edouard Boudinov** (Fortis Bank, Brussels, Belgium), Arkadiy Manevich (Dnipropetrovs'k National University, Ukraine) IC/CT3452/020

In our presentation on GAMM–SIAM Conference on Applied Linear Algebra (Dusseldorf, 2006) a new generalized conjugate direction method for large non-symmetrical linear systems of equations has been proposed. The method unifies advantages of such powerful algorithms as the GMRES and CG methods. Similarly to GMRES and some other Krylov subspace methods for non-symmetrical matrices, the proposed algorithm uses an entire sequence of orthogonal basis vectors, obtained in the Arnoldi process. The Arnoldi process is also used for computing residuals with high accuracy. Unlike GMRES, the method employs explicitly computed conjugate (in a generalized sense) directions to determine iterates. Due to long recurrence and replacement of usual updating residuals with the Arnoldi orthogonalization, the algorithm is found to be very stable and efficient in solving large scale and/or ill-conditioned linear problems.

In this work the extension of the proposed algorithm to solving the linear complementarity problem (LCP) is presented. The problem consists in finding vector x that satisfies the following conditions :

$$\mathbf{A}x \geq \mathbf{b}, \quad x \geq \mathbf{c}, \quad (x - \mathbf{c}) \cdot (\mathbf{A}x - \mathbf{b}) = 0,$$

for a given matrix $\mathbf{A}$ and vectors $\mathbf{b}$ and $\mathbf{c}$.

To examine the efficiency of the proposed method we have applied it to a LCP of financial industry. The partial differential complementarity formulation of the financial option pricing problem leads to a sequence of LCPs. Since both the sequence and dimension of linear systems can be very large and the matrix may be ill-conditioned, the performance of the solver is of great importance. The efficiency of the method is compared with that of the most popular algorithm for solution of the LCP in option pricing – the projected successive overrelaxation method (PSOR).

Krylov-subspace methods for solving complex symmetric shifted linear systems. **Tomohiro Sogabe** (Nagoya University, Japan), Takeo Hoshi (Tottori University, Japan), Shao-Liang Zhang (Nagoya University, Japan), Takeo Fujiwara (University of Tokyo, Japan) IC/CT2614/020

We consider the solution of complex symmetric shifted linear systems of the form $(A + \sigma_k I)\mathbf{x}^{(k)} = \mathbf{b}$, for $k = 1, 2, \ldots, m$, where $A + \sigma_k I$ is a nonsingular N by N complex symmetric matrix with a scalar shift $\sigma_k \in \mathbb{C}$, and $\mathbf{x}^{(k)}, \mathbf{b}$ are complex vectors of length N. Such systems arise in large-scale electronic structure calculations (e.g., [3]), and there is a strong need for the fast solutions of the systems. In this talk, we present the recent development of Krylov subspace methods for solving this class of linear systems. The main talk will concern the shifted COCG method [3], the seed switching technique [2], and the shifted QMR_SYM method that is a variant of the QMR method for complex symmetric linear systems [1].

Preconditioned Krylov-subspace methods for the solution of least-squares problems. **Jun-Feng Yin** (National Institute of Informatics, Japan), Zhong-Zhi Bai (Chinese Academy of Sciences), Ken Hayami (National Institute of Informatics, Japan) IC/CT2396/020

We consider preconditioned Krylov subspace iteration methods, e.g., CG, LSQR and GMRES, for the solution of large sparse least-squares problems $\min \|Ax - b\|_2$, with $A \in \mathbf{R}^{m\times n}$, based on the Krylov subspaces $\mathcal{K}_k(BA, Br)$ and $\mathcal{K}_k(AB, r)$, respectively, where $B \in \mathbf{R}^{n\times m}$ is the preconditioning matrix. More concretely, we propose and implement a class of incomplete QR factorization preconditioners based on Givens rotations and analyze in detail the efficiency and robustness of the correspondingly preconditioned Krylov subspace iteration methods. A number of numerical experiments are used to further examine their numerical behaviour. It is shown that for both overdetermined and underdetermined least-squares problems, the preconditioned GMRES methods are the best for large, sparse and ill-conditioned matrices in terms of both CPU time and iteration step. Also, comparisons with the diagonal scaling and the RIF preconditioners are given to show the superiority of the newly-proposed GMRES-type methods.

Computation of matrix functions in electromagnetic scattering using preconditioned rational Krylov subspaces. **Mikhail Zaslavsky** (Schlumberger Ltd., USA), Leonid Knizhnerman (Central Geophysical Expedition, Russian Federation), Vladimir Druskin (Schlumberger Ltd., USA) IC/CT3091/002

Preconditioning of Krylov subspaces for computing $f(A)b$ is a notoriously difficult problem except when $f(A) = A^{-1}$. We consider electromagnetic scattering problems where A is obtained from the FD discretization of Maxwell's system and we want to approximate $(A + \lambda I)^{-1}b$ for multiple values of the spectral parameter λ using a single rational Krylov subspace. We consider problems with $A = A_0 + A_1$, where A_0 is a "background" operator with easily computable resolvent and A_1 is an "anomaly" operator with local support. The main idea of our approach is the reduction of the subspace approximation from the entire computational domain to the support of A_1. Numerical examples for the 3D low frequency scattering problem show significant acceleration compared to the unpreconditioned subspace.

Skew-symmetric preconditioners for GMRES and BiCG. **Lev Krukier** (Southern Federal University, Russian Federation) IC/CT1928/020

The splitting of the initial matrix in its symmetric and skew-symmetric parts is applied. Then the upper and lower triangular parts of the skew-symmetric matrix are used as the basis for constructing special preconditioners for the solution of strongly nonsymmetric linear systems of equations.

Several theoretical results have been proved. Numerical experiments include the solutions of the strongly nonsymmetric linear equation systems arising from a central finite-difference approximation of the steady convection–diffusion equation with the Peclet numbers $Pe = 10^3$, 10^4 and 10^5. The relative performance of the methods with and without preconditioners for the popular GMRES(10) and BiCG methods have been tested and compared.

Gram–Schmidt orthogonalization: 100 years and more. **Steven Leon** (Univ. of Massachusetts at Dartmouth, USA), Walter Gander (ETH Zürich, Switzerland) IC/CT2697/020

In 1907 Erhard Schmidt published a paper where he introduced an orthogonalization algorithm that has since become known as the classical Gram-Schmidt process (CGS). Schmidt claimed that his procedure was essentially the same as an earlier one published by J. P. Gram in 1883. The Schmidt version was the first to become popular and widely used. The two algorithms produce the same results when carried out in exact arithmetic, however, the Gram version, now known as the modified Gram-Schmidt process (MGS), produces superior results when carried out in finite precision arithmetic. In actuality, Gram rediscovered a method that first appears in an 1816 paper by P. S. Laplace. While the MGS algorithm has been around for almost 200 years, it is the Schmidt paper that led to the popularization of orthonormalization techniques. In celebration of the 100th anniversary of that paper, we present a comprehensive survey of the research on Gram-Schmidt orthogonalization and its related QR factorization.

Structured backward errors and pseudospectra of structured matrix pencils. **Rafikul Alam** (IIT Guwahati, India) IC/CT471/020

Structured pencils occur in many practical applications. Most often, the eigenvalues of structured pencils have certain spectral symmetries and it is very important to preserve these spectral symmetries in the computed eigenvalues. For the accuracy assessment of these computed eigenvalues, it is necessary to develop structured backward error analysis for structured eigenvalue problems. We undertake a detailed structured backward error analysis of a variety structured matrix pencils. We also discuss structured pseudospectra of these structured matrix pencils.

Verifying all eigen-pairs in real symmetric positive-definite generalized eigenvalue problem. **Shinya Miyajima** (Waseda University, Japan), Takeshi Ogita (Japan Science and Technology Agency), Shinichi Oishi (Waseda University, Japan) IC/CT2129/020

In this presentation, we are concerned with the accuracy of computed eigenpairs (eigenvalue λ and its corresponding eigenvector x) in the generalized eigenvalue problem

$$Ax = \lambda Bx$$

where A is a real symmetric matrix and B is a real symmetric positive definite matrix. The generalized eigenvalue problem widely appears in the field of scientific computing, e.g. stationary analysis of circuits, image processing, structure analysis and so forth. In many cases, it is known that A is real symmetric and B is real symmetric positive definite.
There are several methods for calculating guaranteed error bounds for approximate eigenvalues and eigenvectors. Among them, we consider in particular the case of verifying *all eigenpairs*. On verifying a few specified eigenvalues, see the papers by Behnke, Rump, Watanabe et al. and Yamamoto. On verifying a few specified eigenpairs, see the paper by Rump. On verifying all eigenvalues, see the paper by Maruyama et al..

On the other hand, the authors recently proposed a method of calculating guaranteed error bounds for all eigenpairs (μ, y) in the standard eigenvalue problem $Cy = \mu y$, where C is a real symmetric matrix.

In this presentation, we propose a fast method of verifying all eigenpairs for the generalized eigenvalue problem, which is an extension of the previous method by the authors. In the proposed method, intermediate results in the process of verifying all eigenvalues can be reused for verifying all eigenvectors. By this reuse, the computational cost for verifying all eigenvectors becomes almost negligible.

Our numerical results have confirmed that the proposed method supplies error bounds of sufficient quality. They have also confirmed that the computing time for the proposed method is almost the same as that for calculating all approximate eigenpairs.

Parameter analysis of the structure of regular matrix pencils by homotopic deviation theory. **Morad Ahmadnasab** (Universit Toulouse 1 and CERFACS, France) IC/CT1575/020

Let $A, E \in \mathbb{C}^{n\times n}$ be two given matrices, where $\operatorname{rank} E = r < n$. Matrix E is written in the form $E = UV^H$ where $U, V \in \mathbb{C}^{n\times r}$ have rank r. 0 is an eigenvalue of E with algebraic (resp. geometric) multiplicity m (resp. $g = n - r \le m$). We consider the regular pencil $P = (A - zI) + tE$, defined for $t \in \mathbb{C}$ and the parameter $z \in re(A) = \mathbb{C} \setminus \sigma(A)$, where $\sigma(A)$ denotes the spectrum of A.

We analyze how the structure [2] of the pencil P varies as $z \in re(A)$, by means of the notion of *frontier points*, which is essential in Homotopic Deviation theory [1]. At such points, $\operatorname{rank}(M_z) < r$, where $M_z = V^H(zI - A)^{-1}U$ is an $r \times r$ matrix defined for $z \in re(A)$.

When z is not (resp. is) a frontier point, the struture of the pencil P depends only on $r = \operatorname{rank} E$ but not on A (resp. depends on p_z, $1 \le p_z \le r$, the algebraic multiplicity of $0 \in \sigma(M_z)$). As an example, the structure of the regular pencil $A + tE$ when A is nonsingular and $z = 0$, is determined.

Work done in collaboration with Professor F. Chaitin-Chatelin.

Linear perturbation of structured matrix pencils arising in control theory. **Shreemayee Bora** (IIT Guwahati, India), Volker Mehrmann (TU Berlin, Germany) IC/CT2305/020

We develop a framework to analyse the effect of structure preserving linear perturbation on the eigenvalues of matrix pencils arising in linear quadratic optimal control and H_∞-control problems. The results complement and generalize some recent perturbation results for Hamiltonian matrices. The pencils (H, N), associated with the continuous and discrete time linear quadratic optimal control problems have Hamiltonian and symplectic spectral symmetry respectively and it is important to know the smallest structure preserving perturbation so that the perturbed pencil has eigenvalues on the imaginary axis in the former case and on the unit circle in the latter. We obtain necessary and sufficient conditions so that the perturbed pencils $(H + t\Delta H, N + t\Delta N)$, (where $t \in \mathbb{R}$, and ΔH and ΔN inherit the structures of H and N respectively) associated with the continuous time and discrete time versions of the problem have eigenvalues on the imaginary axis and the unit circle respectively. The second motivation is from the optimal H_∞-control problem where the recently developed process of γ-iteration (see [1] for references) involves computation of generalized Schur forms of two different one parameter families of pencils for the continuous and discrete time cases. We show that the parameter of smallest magnitude so that a corresponding pencil has purely imaginary eigenvalues in the continuous time case (respectively eigenvalues of unit modulus in the discrete time case) if it exists is the inverse of the largest real eigenvalue of a matrix much smaller than H or N.

A modified nodal approach to circuit synthesis. **Timo Reis** (TU Berlin, Germany) IC/CT4332/133

A popular result in analytic circuit theory is that for any positive real transfer function $G(s)$, an electrical circuit can be found whose impedance function is $G(s)$. We will reconsider the network realization problem from a differential-algebraic point of view. Given is a descriptor system

$$\begin{aligned} E\dot{x}(t) &= Ax(t) + Bu(t) \\ y(t) &= Cx(t) \end{aligned} \tag{1}$$

with a positive real $G(s) = C(sE - A)^{-1}B$. The aim is to perform state space transformations to (1) such that the resulting system is in modified nodal form, a structured differential-algebraic system arising in circuit modelling. From this form, an electrical circuit with the desired property can be directly constructed.

Adjoint-based quasi-Newton methods for partially separable problems. **Sebastian Schlenkrich** (TU Dresden, Germany), Andrea Walther (TU Dresden, Germany) IC/CT1695/063

Partial separability was introduced by Griewank and Toint (1982) in the context of unconstrained optimization and nonlinear equations. It is based on the assumption that a function $F : \mathcal{R}^n \to \mathcal{R}^n$ can be represented as the sum of individual functions $F_j : \mathcal{R}^n \to \mathcal{R}^n$ for $j = 1 \dots k$. A quasi-Newton algorithm for solving $F(x) = 0$ may exploit the partitioning of F to approximate the Jacobian $F'(x)$ which is characterized by

$$F'(x) = \sum_{j=1}^{k} F'_j(x).$$

Thus sparsity or other structure of $F'(x)$ may be considered by the partitioning and the quasi-Newton method.

In this study the concepts of partitioned quasi-Newton methods are applied to Adjoint Tangent Rank-1 (ATR1) updates. ATR1 updates were introduced by Schlenkrich, Griewank, and Walther (2005). These updates have favorable properties for local and global convergence of the underlying quasi-Newton method. Consequently corresponding partitioned ATR1 updates are presented and local convergence results are established. Numerical results compare the partitioned ATR1 update methods to the corresponding unpartitioned quasi-Newton method and to Newton's method for nonlinear equations.

Direct discretization of the fractional-order differential by using Chebyshev series expansion. **Tsuyako Miyakoda** (Osaka University, Japan) IC/CT3270/021

We evaluate the fractional derivatives of some functions by applying the idea of a indefinite quadrature formula. To do this, we deal with the Chebyshev polynomial of the second kind to achieve the direct approximations to the fractional order(α)differential defined by

$$D^\alpha f(t) = \frac{d^m}{dt^m}\left[\frac{1}{\Gamma(m-\alpha)}\int_0^t \frac{f(r)}{(t-r)^{\alpha+1-m}}dr\right],$$

where $m - 1 < \alpha \le m, m \in N, \alpha \in R^+$. And we try to solve some fractional differential equations.

An hp finite-element method for singularly perturbed systems of reaction–diffusion equations. **Lisa Oberbroeckling** (Loyola College in Maryland, USA), Christos Xenophontos (University of Cyprus) IC/CT2351/021

We consider the approximation of a coupled system of two singularly perturbed linear reaction–diffusion equations, with the finite-element method. The solution to such problems contains boundary layers which overlap and interact and the numerical approximation must take this into account in order for the resulting scheme to converge uniformly with respect to the singular perturbation parameters.
We propose and analyze an hp finite element method which contains thin elements of size $O(p\varepsilon)$ and $O(p\mu)$ near the boundary, with ε and μ the singular perturbation parameters and p the degree of the approximating polynomials. We show that, under the assumption of analytic input data, the method converges at an exponential rate, as $p \to \infty$, independently of the singular perturbation parameters. Numerical results which validate the analysis and compare the proposed method with other schemes found in the literature will also be presented.

Pal-type interpolation on non-uniformly distributed points. **Hanuman Dikshit** (IIIT Jabalpur, India) IC/CT3443/015

Pal-type interpolation problems involving roots of unity and an additional point have been studied extensively. We have in (Numerical Algorithms, 40 (2005), 1-16) studied the regularity of certain Pal-type interpolation problems involving the $m-th$ roots of unity along with an additional point ζ and the $n-th$ roots of unity. We determine the largest domains for ζ, which ensure the regularity of the problems.

Numerical algorithm for a model of neuronal variability. **V.P. Ramesh Venkadachalam** (IIT Kanpur, India) IC/CT5063/021

In this, we analyse numerical approximation of a mathematical model of neuronal variabiliy by R.B. Stein. The model is in general a boundary value problem of singularly pertubed differential difference equation type with small shifts. Algorithm includes an appropriate approximation to the retarted arguments. A parameter uniform difference scheme is discussed. Test examples are solved to demonstrate the efficiency of the numerical scheme and also to show the effect of delays on the solution.

Some numerical methods for approximation of modified Bessel functions . **Juri Rappoport** (Russian Academy of Sciences) IC/CT733/021

Some numerical methods for the approximation of modified Bessel functions are described. The new realization of the Lanczos Tau method with minimal residue is proposed for the numerical solution of the second order differential equations with polynomial coefficients. The computational scheme of Tau method is extended for the systems of hypergeometric type differential equations. A Tau method computational scheme is applied to the approximate solution of a system of differential equations related to the differential equation of hypergeometric type. Various vector perturbations are discussed. The choice of the perurbation term in the form of a shifted Chebyshev polynomial with a special kind of selected transition and normalization is suggested. The minimality conditions for the perturbation term are found for one equation. They are sufficiently simple for the verification in a number of important cases. Several approaches for the computation of kernels of Kontorovitch-Lebedev integral transforms - modified Bessel functions of the second kind with pure imaginary and complex order are elaborated. The codes of the evaluation are constructed and tables of the modified Bessel functions are published. The comparisons are discussed. The advantages of suggested algorithms and codes in accuracy and timing are shown. The effective applications for the numerical solution of some mixed boundary value problems in wedge domains are given.

First applications of a formula for the error of finite sinc-interpolation. **Jean-Paul Berrut** (Université de Fribourg, Switzerland) IC/CT2171/021

We consider the interpolation of a function $f \in C^{2m+2}(\mathbb{R})$ between the equidistant abscissae $x_n = nh$, $h > 0$, $n \in \mathbb{Z}$. Sinc-interpolation is based on a dilation and a series of shifts of the *sinus-cardinalis* function $\mathrm{sinc}(x) := \sin(x)/x$. It often converges very rapidly, so for example for functions analytic in an open strip containing the real line and which decay fast enough at infinity. This decay does not need to be very rapid, however, as in Runge's function $1/(1+x^2)$. Then one must truncate the series, and this truncation error is much larger than the discretisation error (it decreases algebraically as opposed to exponentially for the latter). In 2003 we have discovered a formula for the error $C_N(f,h) - f$ of the truncated series

$$C_N(f,h)(x) := \sum_{n=-N}^{N}{}'' \mathrm{sinc}\left[\frac{\pi}{h}(x-x_n)\right] f_n, \qquad h = \frac{X}{N},$$

for an approximation on the interval $[-X,X]$, where the double-prime means that the first and last terms are halved. The formula reads

$$C_N(f,h)(x) = f(x) + \frac{(-1)^N}{2\pi} \sin\frac{\pi}{h}x \sum_{k=1}^{m} a_{2k}(x)(2h)^{2k} + \mathcal{O}(h^{2m+2}),$$

with

$$a_{2k}(x) := 2(1-2^{-2k})\frac{B_{2k}}{(2k)!}\left[\left(\frac{f(y)}{x-y}\right)^{(2k-1)}(X) - \left(\frac{f(y)}{x-y}\right)^{(2k-1)}(-X)\right]$$

and where the B_k denote the Bernoulli numbers.
In our talk we shall give first applications of the formula, such as its use for correcting $C_N(f,h)$ with derivatives and finite differences, elimination of the Gibbs phenomenon, extrapolation to the limit, the barycentric formula, an error formula for one-sided sinc-interpolation, also.

Nonlocal-means single-frame image zooming. **Mehran Ebrahimi** (University of Waterloo, Canada), Edward Vrscay (University of Waterloo, Canada) IC/CT3505/021

We present a novel single-frame image zooming that combines the ideas of fractal-based image zooming, example-based zooming, and nonlocal-means image denoising in a consistent and improved framework.

The idea of increasing the resolution of an image using its nonlocal self-similarities was initially proposed by the researchers in fractal image coding back in the 1990s. In fractal image coding, one seeks to approximate a target image by the fixed point of a contractive, resolution-independent operator called the fractal transform.

A more recent series of novel example-based methods that take advantage of the self-similarity of images show great promise for the solution of various inverse problems. In 2005, A. Buades et al., demonstrated that their nonlocal-means (henceforth to be referred to as "NL-means") image denoising algorithm has the ability to outperform classical denoising

methods. In this paper, we generalize their method to address the zooming problem.

Similar to NL-means denoising, we compare neighborhoods in the image to predict pixel intensities. Our algorithm compares the neighborhood information of each pixel to the neighborhoods of the same size in the coarser scale over the entire image.

In Bayesian terms, our zooming technique targets the MMSE estimate by learning the posterior directly from examples taken from the image itself at a different scale, similar to fractal-based techniques.

We will address various computational issues and various results of this zooming technique applied to natural images will be presented. Due to the reconstruction scheme, our results do not suffer from the blockiness generally inherent in fractal zooming. Moreover, the geometry of objects is well preserved for the test images presented.

Learning multiresolution schemes for compression of images. **Dionisio Yanez** (Universitat de València, Spain), Paco Arandiga (Universitat de València, Spain), Albert Cohen (Université Paris VI, France) IC/CT3078/021

Learning theory plays a key role in the several scientific fields such as statistics, data mining, artificial intelligence, as well as in some engineering areas. Multiscale decompositions are a well stablished tool that aims at a rearrangement of the information contents in a set of discrete data. Multiresolution transform are based on transfer operators connecting consecutive resolution levels. In this work we apply learning techniques in order to construct one of the key operators of multiscale decompositions within Harten's multiresolution framework: the prediction operator. When applied to the compression of images, 'Learning' can be used to obtain nearly-optimal filters for the prediction process for images on a given library or class. We perform several numerical experiments with these newly designed "learning-multiresolution" transforms and compare our results with the results obtained with other more classical methods.

Exact asymptotics of the uniform error of interpolation by multilinear splines. **Yuliya Babenko** (Sam Houston State University, USA) IC/CT4293/021

In this talk we will investigate the questions of adaptive approximation of C^2 functions by multilinear splines. In particular, we will provide the exact formula to describe the asymptotic behavior of the optimal error of the weighted uniform approximation by interpolating and quasi interpolating splines from this class.

Quasi-interpolation based on bivariate C^1 quadratic B-splines with multiple knots. **Paola Lamberti** (Università degli Studi di Torino, Italy), Catterina Dagnino (Università degli Studi di Torino, Italy), Sara Remogna (Università degli Studi di Torino, Italy) IC/CT1698/021

Taking into account the results[1,2,3] on bivariate spline quasi-interpolation and on the effects of multiple knots[4], in this paper we define, analyse and generate local quadratic spline quasi-interpolants on criss-cross triangulations of a rectangular domain Ω, with possible multiple knots inside Ω and/or on the boundary $\partial\Omega$. Such splines can be particularly useful in mechanics and engineering applications, since they can model constrained surfaces with different kind of smoothness in Ω. A computational procedure for their construction is proposed and some applications with numerical and graphical results are presented.

On Blackman–Harris windows for Shannon sampling series. **Gert Tamberg** (Tallinn University of Technology, Estonia) IC/CT2623/021

A Shannon sampling series is a representation of a function as a function series with its samples as the expansion coefficients. Using different kernels we get generalized sampling series, widely studied at RWTH Aachen since 1977[1]. Sampling theory obeys applications in several disciplines where functions have to be reconstituted from measurements or sampled data. In image processing sampling series give us a natural way to perform operations on images, seen as continuous functions.

In this presentation we consider approximations by the sampling series $C_{W,\mathbf{a}}f$, which are defined by the Blackman–Harris (or cosine-sum) window functions (the Blackman window has been used in signal analysis over 40 years). The choice of parameters $\mathbf{a}$ in Blackman–Harris window allows us to get kernels, suitable for different applications[2,3,4].

We estimate the order of approximation $\|f - C_{W,\mathbf{a}}f\|$ via the modulus of continuity. In the case of certain (m+1)-term cosine-sum window functions the order of approximation can be estimated via the $2m$-th modulus of continuity.

We give also different type of upper and lower bounds for the operator norms of $C_{W,\mathbf{a}} : C(\mathbb{R}) \to C(\mathbb{R})$.

Solutions of Volterra integro-differential equations with rapidly vanishing convolution kernels. **Barbara Zubik-Kowal** (Boise State University, USA), Zdzislaw Jackiewicz (Arizona State University, USA), Frank Hoppensteadt (New York University, USA) IC/CT18/023

Nonlinear systems of Volterra integro-differential equations (VIDEs) of convolution type are studied. Important examples of such problems which motivate our investigations are VIDEs, which model the thalamo-cortical systems describing a new architecture for a neurocomputer.

Such a neurocomputer is modelled in [1] and [2]. The model employs principles of the human brain and is described using systems of VIDEs. Since such a neurocomputer consists of many interconnected units (referred as neurons), the thalamo-cortical systems include large numbers of VIDEs. Therefore, robust and efficient numerical algorithms are needed for computer simulations for the solutions to the systems.

In this presentation, we propose an iteration technique to solve the thalamo-cortical systems numerically. The proposed successive iterates are vector functions of time, which change the original problems into systems of separated equations. Such separated equations can then be solved in parallel computing environments.

We analyze the convergence of the successive iterates by using the properties of the kernels of the thalamo-cortical models. Our theoretical results are confirmed by numerical experiments.

Numerical methods for 2D weakly-singular Volterra integral equations of the second kind. **Alexander Tynda** (Penza State University, Russian Federation) IC/CT723/023

The talk is dedicated to the numerical solution of two-dimensional Volterra weakly-singular integral equations of the form

$$x(t_1,t_2) - \int_0^{t_2}\int_0^{t_1} H(t_1,t_2,s_1,s_2)x(s_1,s_2)ds_1ds_2 = f(t_1,t_2),$$
$$(t_1,t_2) \in D = \{(t_1,t_2) : 0 \le t_1,t_2 \le T,\}$$

which kernels $H(t_1,t_2,s_1,s_2)$ may have two kinds of singularities:

$$H = \frac{h(t_1,t_2,s_1,s_2)}{\left((t_1-s_1)^2+(t_2-s_2)^2\right)^{\alpha}} \qquad H = \frac{h(t_1,t_2,s_1,s_2)}{(t_1-s_1)^{\alpha_1}(t_2-s_2)^{\alpha_2}}.$$

We assume that h and f have continuous derivatives up to certain order $m+1$; $0 < \alpha, \alpha_1, \alpha_2 < 1$.

In order to weaken the singularity influence on the numerical computation we transform the equation in both cases into equivalent equation. The piecewise polynomial approximation of the exact solution is then applied. For numerical computing of the nascent weakly singular integrals we construct the special Gauss-type cubature formula based on nonuniform grid.

Also we suggest the practical mesh which is less nonuniform than standard graded mesh $t_k = \left(\frac{k}{N}\right)^{r/(1-\alpha)} T$, but at the same time it gives us an equivalent approximation error for the functions from $C^{r,\alpha}(0,T]$.

Economical discretization schemes in the finite-section method. **Evgeniya Lebedeva** (Ukraine, Kiev), Sergei Solodky (Institute of Mathematics, Kiev, Ukraine) IC/CT1516/023

Consider a first-kind Fredholm integral equation

$$Az(t) := \int_0^{\infty} k(t,\tau)b(\tau)(1+\tau)^{-s/2}z(\tau)d\tau = y(t). \quad (1)$$

where $z(t), y(t) \in L_2(0,\infty)$, $k(t,\tau), b(\tau) \in C(0,\infty)$ and $|k(t,\tau)| \le c_k[(1+t)(1+\tau)]^{-\kappa}$, $|b(\tau)| \le c_b\tau^{\beta}$, $\kappa > 1/2$, $s > 2\beta - 2\kappa + 1$. Suppose that $y_\delta(t) \in L_2(0,\infty)$ is known instead of $y(t)$ and $\|y - y_\delta\|_{L_2(0,\infty)} \le \delta$. Let $a(t,\tau) := k(t,\tau)b(\tau)(1+\tau)^{-s/2}$ satisfies the conditions $|a^{(i,j)}(t,\tau)| \le c(1+t)^{-\alpha}(1+\tau)^{-\omega}, i,j = 0,1$ at some $\alpha,\omega > 1/2$. Many inverse problems in optic and astronomy are described by the equation (1) (see [1]).

Let P_M be an orthoprojector from $L_2(0,\infty)$ to $L_2(0,M)$. According to finite-section method we pass from (1) to the equation

$$P_{2^n}AP_{2^m}z(t) := \int_0^{2^m} a(t,\tau)z(\tau)d\tau = P_{2^n}y_\delta(t), t \in [0,2^n),$$

Consider the system of knots $t^{\theta}_{0,q,i} = i2^{-q}$, $t^{\theta}_{k,q,i} = 2^{k-1} + i2^{k-1}M^{-1}_{k,\theta}$, $k = 1,2,3,...,i = 0,1,...M_{k,\theta}$, $M_{k,\theta} = [2^{k(1-\theta)+q}]$. Here $0 < \theta \le 1$ and $q \in N$ are some fixed numbers, $[u]$ is integer part of u. Let's construct a function interpolating $a(t,\tau)$ at the points of grid above:

$$S^q_{k,l}(a;t,\tau) = \sum_{i=1}^{M_{k,\theta_1}}\sum_{j=1}^{M_{l,\theta_2}} a(t^{\theta_1}_{k,q,i-1}, \tau^{\theta_2}_{l,q,j-1})S_{k,i}(t)S_{l,j}(\tau), \quad (2)$$

where $S_{k,i}, S_{l,j}$ are characteristic functions of the intervals $[t^{\theta_1}_{k,q,i-1}, t^{\theta_1}_{k,q,i})$ and $[t^{\theta_2}_{l,q,j-1}, t^{\theta_2}_{l,q,j})$. Denote the total volume of values for $a(t^{\theta_1}_{k,q,i}, \tau^{\theta_2}_{l,q,j})$ as Card. A scheme with smaller quantity of Card is called more economical. As is well known, for achievement of order-optimal error it is necessary to approximate $P_{2^n}AP_{2^m}$ with accuracy $O(\delta)$.

Statement of problem. It is required to construct economical discretization scheme of operator $P_{2^n}AP_{2^m}$ so that the kernel of finite-dimensional operator A' is a sum of functions (2) and $\|A' - P_{2^n}AP_{2^m}\| = O(\delta)$.

Suppose $\mu = \kappa - 1/2$, $\lambda = \kappa + \frac{s}{2} - \beta - \frac{1}{2}$, Let $\mu > \lambda$, then at $m > n$ we fix $\forall d \in R : 1 < d < \min\{\frac{\mu}{\lambda}, \frac{m}{n}\}$. Let's construct the kernel of operator A' as $\sum_{k=1}^{n}\sum_{l=1}^{m-dk} S^q_{k,l}(a;t,\tau) + \sum_{k=1}^{n} S^q_{k,0}(a;t,\tau) + \sum_{l=1}^{m} S^q_{0,l}(a;t,\tau) + S^q_{0,0}(a;t,\tau)$.

Theorem. *If m,n,q are such that $2^m \asymp \delta^{-\frac{1}{\lambda}}, 2^n \asymp \delta^{-\frac{1}{\mu}}, 2^q \asymp \delta^{-1}\sqrt{\log(1/\delta)}$, then A' satisfies condition above and order bounds for* Card *hold true a) $\delta^{-2}\log^3\frac{1}{\delta}$, if $\theta_1 = \theta_2 = 1$; b) $\delta^{-2-\frac{1-\theta_1}{\mu}}\log^2\frac{1}{\delta}$, if $\theta_1 < 1$, $\theta_2 = 1$ or $\theta_1 < \theta_2 < 1$, $d = \frac{1-\theta_1}{1-\theta_2}$; c) $\delta^{-2-\frac{1-\theta_2}{\lambda}}\log\frac{1}{\delta}$, if $\theta_1 = 1$, $\theta_2 < 1$ or $\theta_1 < \theta_2 < 1$, $d > \frac{1-\theta_1}{1-\theta_2}$ or $\theta_2 < \theta_1 < 1$ or $\theta_1 = \theta_2 < 1$; d) $\delta^{-2-\frac{1-\theta_2}{\lambda}-\frac{1-\theta_1-d(1-\theta_2)}{\mu}}\log\frac{1}{\delta}$, if $\theta_1 < \theta_2 < 1$, $d < \frac{1-\theta_1}{1-\theta_2}$.*

At $\theta_1 + \theta_2 < 2$ proposed scheme is more economical as compared to standard one[1]. For $\lambda \ge \mu$ new economical discretization schemes have also been constructed.

A fast algorithm for the inversion of boundary integral operators. **Per-Gunnar Martinsson** (University of Colorado at Boulder, USA) IC/CT3211/023

In this talk, we will present a fast algorithm that directly constructs a compressed representation of the inverse of an integral operator. When applied to boundary integral equations in two dimensions involving non-oscillatory or moderately oscillatory kernels, the computational complexity of the scheme is $O(N)$, where N is the number of degrees of freedom in the discretization.

Through several computational examples, we will demonstrate that the algorithm can effectively solve integral equations that are not well-suited for iterative solvers, such as scattering problems involving cavities. We will also show that for problems involving multiple right-hand-sides, the scheme is between one and two orders of magnitude faster than iterative solvers based on the Fast Multipole Method.

A generalization to an algorithm for inverting boundary integral operators in three dimensions will be discussed, as well as methods for rapidly computing spectral decompositions of integral operators. Furthermore, comparisons will be made with similar schemes that have been published by other authors in the last ten years.

Work done in collaboration with Vladimir Rokhlin and Mark Tygert.

Order stars and order arrows. **John Butcher** (University of Auckland, New Zealand) IC/CT3375/024

The use of order stars in the analysis of stability questions is well-known. In particular, the Ehle barrier was first proved using this approach. This and related results can sometimes also be proved using "Order arrows" and a survey of this alternative technique will be presented. Given a sequence of integers $[n_0, n_1, \ldots, n_r]$, a generalized Padé approximation to the exponential fiunction is a sequence of polynomials $(P_0, P_1, \ldots, P_r)$ such that $\sum_{i=0}^{r} \exp((r-i)z)P_i(z) = O(z^{p+1})$, where the order p is equal to $\sum_{i=0}^{r}(n_i+1)-1$. Using a definition of A-stability related to the application of these approximations to multivalue methods for the solution of initial value poblems, it was conjectured by F. Chipman and the author that $2n_0 \le p+2$ is a necessary condition. In the case $r=1$, this is the Ehle barrier. A proof of the general case $r \ge 1$ will be presented.

The reliability/efficiency trade-off for a new class of ODE solvers. **Wayne Enright** (University of Toronto, Canada) IC/CT2433/024

In the numerical solution of ODEs, it is now possible to develop efficient techniques that will deliver approximate solutions that are piecewise polynomials. The resulting methods can be designed so that the piecewise polynomial will satisfy a perturbed ODE with an associated defect (or residual) that is directly controlled in a consistent fashion. We will discuss the reliability/efficiency trade off that one faces when implementing and using such methods. In particular we will identify a new class of continuous Runge–Kutta methods with a reliable defect estimator and a validity check that reflects the credibility of the estimate.

Numerical results on a wide selection of problems will be summarised for methods of orders four through eight. It will be shown that a modest increase in the cost per step can lead to a significant improvement in the robustness and reliability of the method.

Convergence of the generalized-α method applied to differential-algebraic equations of index 3 . **Martin Arnold** (Universität Halle–Wittenberg, Germany) IC/CT3364/024

The generalized-α method belongs to the class of Newmark type methods that are frequently used for the time integration of finite element models in structural dynamics. Recently, these methods have also been applied successfully in multibody dynamics to solve numerically the equations of motion of constrained mechanical systems.

In the present paper, the application of the generalized-α method to a class of second order differential-algebraic equations of index 3 is considered in more detail (see also M. Arnold, O. Brüls: *Convergence of the generalized-α scheme for constrained mechanical systems.* - accepted for publication in: Multibody System Dynamics, 2007). Convergence is analysed using an equivalent multistep representation of the method. Second-order convergence is demonstrated for all solution components including the algebraic ones.

From a practical viewpoint, the application of these results to the index-3 formulation of the equations of motion for constrained mechanical systems is of particular interest. Numerical tests for a benchmark problem illustrate practical implications of the convergence analysis.

Analysis of a multirate θ-method for stiff ODEs. **Valeriu Savcenco** (CWI, Amsterdam, The Netherlands) IC/CT4565/024

To solve ODE systems with different time scales which are localized over the components, multirate time stepping can be used. We present a study of a simple multirate scheme, consisting of the θ-method with one level of temporal local refinement. Issues of interest are local accuracy, propagation of interpolation errors and stability. The theoretical results are illustrated by numerical experiments, including results for more levels of refinement with automatic partitioning.

Dynamic optimization and nonlinear differential–algebraic equations in computational chemistry. **Alexandre Caboussat** (University of Houston, USA), Jiwen He (University of Houston, Switzerland), Chantal Landry (École Polytechnique Fédérale de Lausanne, Switzerland) IC/CT2448/024

Dynamic optimization problems arise when coupling an optimization problem with ordinary differential equations. This problem appears for instance in computational chemistry when a system at equilibrium exchanges mass with a surrounding media. A stiff system of differential-algebraic equations is obtained when replacing the optimization problem with its first order optimality conditions.

In this talk, we discuss numerical methods for the efficient resolution of a system of differential-algebraic equations arising in the modeling of the dynamics of atmospheric organic aerosol particles. The minimization of the Gibbs free energy with equality and inequality constraints is coupled with differential equations when the constraints of the optimization problem depend on time.

The static minimization problem consists in computing the convex envelope of the energy. We propose a primal-dual interior-point method for the determination of this global optimum and introduce the notion of phase simplex related to

the convex envelope to describe mathematically the optimum. We solve the Karush-Kuhn-Tucker system of nonlinear equations that consists of the first order optimality conditions. Efficient numerical linear algebra methods, using Schur complement and null-space methods, are designed for the resolution of the resulting Newton system.

We extend the methodology to the time-variable optimization problem arising when the optimization problem is coupled with differential equations. The first order conditions, together with an implicit discretization of the differential equations, form an extended system that is solved with sequential quadratic programming techniques, by controlling the inertia of the linear system. The detection of discontinuities in the trajectories, due to the inequality constraints in the optimization problem, are discussed. Numerical results are presented for the computation of the thermodynamic equilibrium and mass transfer of organic aerosols.

A note on the error growth in the numerical integration of periodic orbits. **Juan Ignacio Montijano** (Universidad de Zaragoza, Spain), Manuel Calvo-Pinilla (Universidad de Zaragoza, Spain), Pilar Laburta (Universidad de Zaragoza, Spain), Luis Rández (Universidad de Zaragoza, Spain) IC/CT4068/024

Periodic and small perturbations of periodic solutions appear frequently associated to systems of differential equations in many applications. There has been a considerable amount of work investigating how numerical integrators perform on periodic orbits, in particular in the long-time integration. Thus B. Cano and J. M. Sanz-Serna (SIAM J. Numer. Anal. , 1997) analyze the growth of the global error in the numerical integration with one-step methods of such class of problems, with special attention to Hamiltonian and reversible systems.

The aim of this work is to extend this analysis in two ways. On one side considering systems with a periodic solution embedded into a family of periodic orbits. More precisely, for each $\hat{x}$ in a neighborhood of the initial condition x_0, the solution of $x' = f(x)$, $x(0) = \hat{x}$ is also periodic with period $T = T(x)$ where the function T is as smooth as required. For this class of problems we show that the monodromy matrix of $x(t)$ can be expressed in terms of the gradient $\nabla T(x_0)$ and that the global error after N periods $ge^{(N)}$ is affected by a linear term $Nge^{(1)}$ and a quadratic term in N whose coefficient depends on $\nabla(x)^T ge^{(1)}$. It is shown that if the period depends only on some invariants of the problem and the numerical method preserves these invariants, the global error behaves as $\mathcal{O}(N)$. On the other hand we study the behavior of the error in the invariants when a problem with some conservation property and periodic solution is integrated. We show that for most one-step methods the invariant error behaves as $\mathcal{O}(N)$.

Computation of the Mittag-Leffer matrix function that arises in fractional differential equations. **Roger Sidje** (University of Queensland, Australia) IC/CT4803/024

Although not as widely known as other special functions, the Mittag-Leffer function, which is a generalization of the exponential function, is gaining prominence owing to its usefulness when modelling certain physical and biological processes with anomalous diffusion. Such processes are formulated in terms of derivatives (and integrals) of fractional (non-integer) order. Of particular interest is the development of numerical methods for computing the Mittag-Leffer function, especially in the case where its argument is a matrix of potentially large dimension. We discuss Krylov subspace techniques and related issues to address this problem.

On collocation method by orthogonal 0-interpolants. **Muhammad Bokhari** (King Fahd University, Saudi Arabia), Hussain Al-Attas (King Fahd University, Saudi Arabia) IC/CT3510/024

Most of the engineering and scientific problems give rise to boundary value problems for which the method of finding analytic solution is either very complicated or sometimes impossible. The collocation methods are widely used to determine approximate solution of such problems. Among these the orthogonal collocation method is quite prominent. This method leads to fourth order convergence. Recently, we have introduced the notion of orthogonal 0-interpolants and applied it to determine certain constrained approximation problems. These interpolants have free zeros like the standard orthogonal polynomials and also some pre-assigned zeros. Here, we discuss a collocation method based on a combination of fixed and free zeros of orthogonal 0-interpolants. We shall present an outcome of comparative study of our suggested method with the standard orthogonal collocation method.

Absolutely-stable explicit schemes for reaction systems. **Chang-Ock Lee** (KAIST, Republic of Korea), Eun-Hee Park (KAIST, Republic of Korea), Jae Boum Youm (Inje University, Republic of Korea), Chae Hun Leem (University of Ulsan, Republic of Korea) IC/CT2859/024

Many phenomena of interest in physiology and biochemistry are characterized by reactions among several chemical species and diffusion in various mediums. In a closed system, both reactions and diffusion are governed by a system of ordinary differential equations (ODEs)

$$\dot{\mathbf{y}}(t) = M\mathbf{y}(t), \tag{1}$$

which guarantees conservation of the total amount of $\mathbf{y}(t)$ for any $t \geq 0$. Since we are concerned with the steady-state solution as well as the transient in simulations of very large systems of chemical reactions or molecular dynamics, we need to take the overall computational cost into consideration. Many physiologists and biochemists prefer explicit methods to implicit methods since implementation of the explicit methods is easier than the others. The popular methods for reaction systems are simple explicit schemes such as Euler's method, Runge-Kutta method, etc. However, it is well-known that conditional stability, the typical weak point of explicit methods, is very fatal for stiff problems. In the past few decades, many studies on numerical methods for stiff ODEs have been done in various aspects.

The aim of this talk is to present two absolutely stable explicit schemes which are applicable to a general reaction system (1). The proposed methods are motivated by the simple exact solver for a reversible reaction. In spite of their explicitness, we have unconditional stability, that is, stability without any condition on the step size. Furthermore, we proved the convergence of the proposed methods; one is of first order and the other is of second order.

Adaptive τ method for ODEs. **Seyed Mohammad Hosseini** (Tarbiat Modares University, Iran) IC/CT198/024

The Tau method for solving differential equations has been the topic of research in last 30 years. For ordinary differential equations over long intervals and particularly for stiff equations it requires very small step lengths and so it is not generally successful. We introduce an adaptive strategy with which this method can solve stiff odes efficiently. In this work we discuss and compare different merits of variable and fixed time step Tau method.

Numerical solution of fractional differential, integral and integro-differential equations by using piecewise-constant orthogonal functions. **Ali Salimi Shamloo** (Islamic Azad University of Shabestar, Iran), Esmaeil Babolian (Tarbiat Moallem University, Iran) IC/CT4339/002

In this paper, we use operational matrices of piecewise constant orthogonal functions on the interval $[0,1]$ to solve fractional differential, integral and integro-differential equations. We first use operational matrices and then convert the problem to a system of linear equations. Numerical examples show that the approximate solutions have a good degree of accuracy.

Keywords: Fractional differential equations, Fractional integral equations,Fractional integro-differential equations, Piecewise constant orthogonal functions, Operational matrices.

Numerical solution of the system of Fredholm integro-differential equations by the τ method. **Jafar Pourmahmoud Gazijahani** (Azarbijan University of Tarbiat, Iran), Sedghat Shahmorad (University of Tabriz, Iran) IC/CT664/023

The τ method, produces approximate polynomial solution of differential, integral and integro-differential equations (see [E.l,Ortiz, The Tau method, SIAM J. Numer. Anal. 6 (3) (1969) 480Ű492; E.l. Ortiz, H. Samara, An operational approach to the Tau method for the numerical solution of non-linear differential equations, Computing 27 (1981) 15Ű25; S.M. Hosseini, S. Shahmorad, A matrix formulation of the Tau for Fredholm and Volterra linear integro-differential equations, The Korean J. Comput. Appl. Math. 9 (2) (2002) 497Ű507; S.M. Hosseini, S. Shahmorad, Numerical solution of a class of integro-differential equations by the Tau method with an error estimation, Appl. Math. Comput. 136 (2003) 559Ű570]). In this paper, we extend the Tau method for the numerical solution of integro-differential equations systems (IDES). We also give a brief description of the structure of the Tau program by the Maple software. An efficient error estimation of the numerical solution of the method is also introduced. Some examples are given to clarify the efficiency and high accuracy of the method.

Keywords: Operational Tau method; Integro-differential equations

Organiser: Christina Christara (University of Toronto, Canada)

On the free-boundary formulation for parabolic problems. **Salvatore Iacono** (Università degli Studi di Messina, Italy), Riccardo Fazio (Università degli Studi di Messina, Italy) IC/CT3997/025

The aim of this paper is to propose an original numerical approach for parabolic problems whose governing equation are defined on an infinite domain. We are interested in analysing the class of problems admitting invariance property to Lie group of scalings. Thanks to similarity analysis, in such a way the parabolic problem can be transformed to an equivalent boundary value problem governed by an ordinary differential equation and defined on an infinite interval. A free boundary formulation and a convergence theorem for this kind of transformed problems are available in [Fazio, SIAM J. Numer. Anal., 33 (1996), pp. 1473-1484]. Depending on its scaling invariance properties, the free boundary problem is then solved numerically using either an iterative or non-iterative method. Finally, the solution of the parabolic problem is retrieved applying the inverse map of similarity.

Finite-element method for semilinear parabolic interface problems. **Rajen Sinha** (IIT Guwahati, India) IC/CT238/025

We study the convergence of finite element solution to the exact solution of a semilinear parabolic interface problem in a two dimensional convex polygonal domain. If the triangulation is isoparametrically fitted to the interface then optimal order error estimate is achieved in $L^2(H^1)$-norm for the semidiscrete scheme. Based on backward Euler method, a fully discrete scheme is also analyzed and the related convergence result is established. The interface is assumed to be of arbitrary shape and is smooth for our purpose.

Flux-based level-set method: a finite-volume method for evolving interfaces. **Christian Wehner** (Universität Heidelberg, Germany) IC/CT3665/025

The flux-based level-set method is a finite volume method for solving hyperbolic equations arising in the level-set formulation of interface evolution. The motion can be defined by an external velocity field or by a velocity depending on the normal direction of the interface. The method is second-order accurate for smooth solutions and shows good behaviour in more involved cases like deformation flow fields or expanding square.

Several applications will be presented, including the modeling of convection-diffusion in two-phase flow, reinitialization of the level-set function an the problem of sail-boat distances. The simulations are realized using Matlab.

Spline collocation for parabolic partial differential equations. **Christina Christara** (University of Toronto, Canada) IC/CT3146/025

Collocation is a simple to implement discretization technique for differential equations' problems that gives an approximation to the solution over the whole domain of the problem. Spline collocation has been primarily used for the solution of Boundary Value Problems for ODEs or PDEs, and shown to be an effective method. Two types of spline collocation methods have been developed, the extrapolated (a.k.a. modified) and the deferred-correction methods, both giving rise to optimal order of convergence to the solution. These methods have been extended recently to non-uniform grids and integrated with adaptive techniques. In this presentation, we are concerned with spline collocation methods for parabolic PDEs. In particular, we consider quadratic and cubic spline collocation formulated as deferred-correction methods and combined with finite difference time discretization techniques. Deferred-correction methods normally require the solution of two linear systems per timestep. We discuss ways to avoid the solution of the second linear system, thus improving the efficiency of the methods, without sacrificing accuracy and stability. We also present the difficulties to incorporate adaptive techniques in the space dimension(s), while maintaining the efficient formulation of the methods and suggest ways to overcome them.

Adaptive techniques for parabolic problems using deal.II software. **Nupur Gupta** (IIT Bombay, India), Neela Nataraj (IIT Bombay, India), Andreas Griewank (Humboldt-Universität zu Berlin, Germany) IC/CT3639/025

The work is based on finding error control and adaptive mesh designing for evolution problems in 2 dimensions. For numerical results the software deal is being used and memory consumption issue is also discussed. Error estimators are also being calculated using duality argument as in priori error estimates.

Numerical propagator method solutions for the linear parabolic initial boundary-value problems. **Janis Rimshans** (Latvijas Universitate, Latvia), Sharif Guseynov (Latvijas Universitate, Latvia) IC/CT3029/025

Solubility of the linear initial-boundary value problem containing lower order derivatives is discussed. Initial-boundary value problem is formulated as follows:

$$\partial_t C = \nabla \cdot D\nabla C + f(\nabla C, C, t, x), \qquad in \quad \Omega, \tag{1}$$

$$D\nabla C \cdot \nu + \gamma C = \vartheta(t), \qquad on \quad \partial\Omega, \tag{2}$$

$$C(0,x) = C_0(x), \tag{3}$$

where D is bounded and positive defined, γ and ϑ are given functions.

By using Green function approach analytical solution consistent with solubility conditions of the problem is formulated for the case of constant coefficients of parabolic equation. On the base of numerical propagator method a new finite volume difference scheme is proposed. Stability of the scheme is investigated taking in to account obtained analytical solutions of the initial-boundary value problem $(1)--(3)$. Numerical tests are presented.

Lagrange-projection scheme for two-phase flows: 1. application to realistic test cases. **Quang Long Nguyen** (Institut Français du Pétrole, France), Frederic Coquel (Université Pierre et Marie Curie, France), Marie Postel (Université Pierre et Marie Curie, France), Quang Huy Tran (Institut Français du Pétrole, France) IC/CT2286/025

We are concerned with the numerical simulation of two-phase flows representing oil transportation along a 1-D pipeline. More specifically, we wish to show that, for this kind of problems, it is highly recommended to make use of the Lagrange-Euler projection formalism. Indeed, this approach naturally splits the effects of slow (kinematic) and fast (acoustic) waves, thus enabling us to design a numerical scheme with several desirable properties:

- explicit with respect to slow waves (for which a great accuracy is expected by engineers, since transportation is the one and only phenomenon of interest),
- implicit with respect to fast waves (for which not so much accuracy is required, since pressure propagation is a usually disregarded phenomenon),
- locally conservative, which makes it ready for adaptive mesh refinement,
- positivity preserving for the density and mass fractions.

The design of the overall implicit-explicit Lagrange-projection method involves many interesting mathematical details. These will be elaborated on in the joint contributing talk by Dr. Q.H. Tran. In this paper, the emphasis will be laid on the motivation and the general philosophy of the proposed technique. Efficiency of the multiresolution method for time adaptive mesh design is also assessed in this setting. Extensive numerical results for realistic test cases are then presented in order to illustrate the capabilities of the resulting method.

Control analysis for water-quality problem. **Mohammed Louaked** (Université de Caen, France) IC/CT1674/025

Analysis of the environmental impact of waste water discharges into aquatic media takes a great importance in the last years. The problem considered here is in the field water-quality improvement by varying the systems, such as flow regulation by means of reservoirs. The creterion functional to be minimized penalizes deviation of phaecal coliforms distribution from standard value. We adress exact and approximate controllability problems for a parabolic equation (evolution of pollutant concentration) associated with Dirac measures.
Hybrid numerical methods combining particle method and finite difference method is presented. Symmetric TVD scheme for the shallow water equations, in general coordinates, is used. The technique is an hybrid method that uses the second order flux in smooth regions but involves some limiting based on the gradient of the solutions so that near discontinuities it reduces to the monotone upwind method. A particle method is proposed to handle the parabolic equation. The difficulty is then to deal with a diffusion term. We analyze an approach based on a purely deterministic method. The approximation of the diffusion operator is based on the introduction of boundary integral equation formulation. The gradient of the cost function is evaluated by adjoint techniques and the quasi-Newton as an iterative solution of the discrete control problem is choosen.
The major issue of the numerical part relies on illustrating by direct simulation the effectiveness of this methodology when applied to the control of water quality problem. Relative merits and advantages of this approach are explored.

Fast algorithms for PDEs in simple and complex geometries. **Prabir Daripa** (Texas A&M University, USA) IC/CT708/026

Solving problems in complex geometries efficiently and accurately are important from practical as well as from fundamental viewpoint. Some numerical methods for solving such problems involve use of domain embedding in combination with fast solvers for regular geometries. The speakers in this minisymposium will describe fast algorithms for regular geometries as well as for complex geometries using a variety of techniques within the above framework. A fast algorithm based on the representation of solutions of PDEs in terms of Green's function in regular geometries and its efficient adaptation for solving problems in complex geometries in combination with domain embedding will also be presented.

Numerical simulation of three-dimensional grain growth in materials containing finely dispersed second-phase particles with the phase field method. **Liesbeth Vanherpe** (Katholieke Universiteit Leuven, Belgium), Nele Moelans (Katholieke Universiteit Leuven, Belgium), Bart Blanpain (Katholieke Universiteit Leuven, Belgium), Stefan Vandewalle (Katholieke Universiteit Leuven, Belgium) IC/CT1889/025

The microstructure of materials often consists of multiple grains with different crystallographic orientations. The study of the evolution of the grains is of great technological importance because many material properties depend on the mean grain size. A common technique to control the grain size of a material is the addition of impurities which leads to the formation of small second-phase particles that will stop the grain growth. The limiting grain size depends on the number, size, shape and spatial distribution of the particles.

We employ a phase field model for simulating three-

dimensional grain growth in materials containing small incoherent second-phase particles which consists of a large set of coupled reaction-diffusion partial differential equations. A fine threedimensional grid is required to resolve the particles and the shape of the grain boundaries. Moreover, a large number of grains and particles should be considered to achieve statistically relevant results. As such, a typical simulation demands extensive computer resources both with respect to memory and computing time.

There are several ways to speed up the computations. We will present two techniques, one using a semi-implicit discretization resulting in an explicit coupling between the partial differential equations so equations can be assigned to different processes and solutions can be computed in parallel. The second technique evolved through a study of the model which revealed that the solutions of the model display small regions of high activity surrounded by large regions of inactivity. This property is exploited through the second technique as we define bounding boxes around the regions of high activity and only solve the equations locally. This algorithm has low memory and computing time requirements.

Multipoint non-local boundary-value problems for Schrödinger equation. **Ali Sırma** (Gebze Institute of Technology, Turkey), Allaberen Ashyralyev (Fatih Üniversitesi, Turkey) IC/CT595/025

In present paper the multi-point nonlocal boundary value problem with integral for Schrödinger equation in a Hilbert space H with the self-adjoint operator A is considered. The stability estimates for the solution of this problem is established. Two multipoint nonlocal boundary value problems with integral are investigated. The first and second order of accuracy difference schemes for the approximate solutions of this nonlocal boundary value problem are presented. The stability of these difference schemes is established. In practice, the stability inequalities for the solutions of difference schemes for Schrödinger equation are obtained. A numerical method is proposed for solving a one-dimensional Schrödinger equation with nonlocal boundary condition. A procedure of modified Gauss elimination method is used for solving these difference schemes. The method is illustrated by numerical examples.

Theory and applications of the DGFEM for nonlinear convection–diffusion problems. **Miloslav Feistauer** (Univerzita Karlova, Czech Republic) IC/CT1228/025

In this paper we shall be concerned with several aspects of the numerical solution of convection-diffusion problems by the discontinuous Galerkin finite element method (DGFEM) and applications to compressible flow. The DGFEM is based on a piecewise polynomial approximation of the sought solution without any requirement on the continuity on interfaces between neighbouring elements. It is particularly convenient for the solution of conservation laws with discontinuous solutions or singularly perturbed convection-diffusion problems with dominating convection, when solutions contain very steep gradients.

First subject of our paper is the analysis of L^2-optimal error estimates of the DGFEM applied to nonstationary problems with a nonlinear convection as well as diffusion. The attention will be paid to the DG space semidiscretization and for the DG space discretization combined with backward difference formula used for the time stepping. The theoretical results will be illustrated by numerical experiments.

In the second part, some applications of the DGFEM to the simulation of compressible flow, i.e. the solution of the compressible Euler and Navier-Stokes equations, will be presented. Our goal is to develop sufficiently accurate, efficient and robust numerical schemes allowing the solution of compressible flow for a wide range of Reynolds and Mach numbers. Our approach allows to solve gas flow with practically all Mach numbers (starting from Mach number $= 10^{-6}$ up to transonic regimes). The efficiency and accuracy of the method will be demonstrated by computational results for some technically relevant test problems.

A discontinuous Galerkin approach to the Wigner equation with a non-polynomial basis. **Richard Sharp** (University of Texas at Austin, USA) IC/CT906/024

The dynamics of semiconductor devices and other quantum systems, including interaction with their environment, can be modeled by the Wigner equation and an appropriate collision operator. Previous numerical methods have relied on operator splitting methods. We provide a new approach for simulations built on the Discontinuous Galerkin (DG) method with an arbitrary (non-polynomial) basis. The use of a non-polynomial approximation spaces for DG calculations has recently been proposed by Yuan and Shu. In the context of the Wigner equation, this allows the introduction of a basis tailored to the highly oscillatory solution which develops when a sharp potential is encountered.

Discontinuous Galerkin relaxation algorithm for solute transport in porous media. **Mohammed Mahmood** (Žalinská univerzita, Slovakia) IC/CT3756/025

We consider a degenerate parabolic convection dominated equation which models the transport of contaminant in porous media. The numerical scheme is fulfilled by combining the DG - Discontinuous Galerkin Method with and an efficient relaxation algorithm that recently developed. Numerical results show the efficiency of our scheme.

An accuracy analysis of mass-matrix lumping for 3D unsaturated flow, finite-element, porous-media computations using analytical solutions. **Fred Tracy** (US Army Corps of Engineers, USA) IC/CT433/025

Lumping of the mass matrix for transient problems is the state of the practice for finite element groundwater programs. This improves nonlinear convergence where there is unsaturated flow, but the discovery was made that the accuracy of the results is reduced as much as an order of magnitude for a test problem. This presentation compares results from a recently derived transient three-dimensional (3-D) analytical solution for the given unsaturated flow test problem (Tracy, 2006) with those from a standard parallel Galerkin 3-D finite element groundwater program with the mass matrix lumping option turned both on and off.

A description of the test problem and equations for the analytical solution will also be presented. The test problem consists of transient flow into a rectangular block of initially dry soil until water is applied at the top. Because Richards' equation for describing unsaturated flow in porous media is highly nonlinear, testing is challenging for 3-D finite element groundwater programs. However, accuracy and performance results for these programs can be easily obtained using the analytical solution. Also, the amount of nonlinearity of the analytical solution can be easily adjusted by a parameter α. Accuracy results for various sizes of the mesh and for three values of α of the 3-D test problem from runs made with and without mass matrix lumping are presented. As α is increased, the accuracy of the solution is decreased. Results for grids as large as $161 \times 161 \times 161$ are computed by using as many as 512 processing elements on the U.S. Army Engineer Research and Development Center Major Shared Resource Center Cray XT3.

Finally, this presentation concludes with parallel performance results obtained in the following study.

[1] Tracy, F.T.; Clean two- and three-dimensional analytical solutions of Richards' equation for testing numerical solvers. Water Resour. Res., 42, W08503, (2006). doi:10.1029/2005WR004638.

Finite-element discretization of parabolic–elliptic interface problems. **Marcus Stiemer** (Universität Dortmund, Germany) IC/CT2783/025

In this presentation mixed boundary value problems for partial differential equations are considered that are parabolic in one part of the underlying domain and elliptic in another part. On the interface of the region of elliptic and parabolic behavior a jump condition for the Neumann traces is given. Such interface problems occur in eddy current simulations in electrodynamics. The fully discrete scheme applied to compute an approximative solution of the mixed problem is based on a spatial discretization with edge elements and a temporally discontinuous Galerkin method. Its convergence is proven and *a priori* error estimates are given. Moreover, adaptive schemes based on *a posteriori* error control are presented.

Efficient numerical schemes for singularly-perturbed parabolic initial boundary-value problems. **Natesan Srinivasan** (IIT Guwahati, India), Rajdeep Deb (IIT Guwahati, India) IC/CT483/025

In this article, we consider the time-dependent singularly-perturbed reaction–diffusion problems of the form $-\varepsilon u_{xx} + b(x,t)u(x,t) + d(x,t)u_t = f(x,t)$, $(x,t) \in (0,1) \times (0,T]$, where $0 < \varepsilon \ll 1$, subject to initial and boundary conditions. These problems arise in several branches of engineering and applied mathematics which include fluid dynamics, quantum mechanics, elasticity, chemical reactor theory, etc. In general, the solution $u(x,t)$ exhibit boundary layers of parabolic type along the sides $x = 0$ and $x = 1$. A careful examination of numerical computations shows that usually the point-wise error in the numerical solution actually increases, as the mesh size $\triangle x$ is refined to the stage where $\triangle x$ is of the same order of magnitude as ε.

To solve these types problems, we propose two efficient numerical schemes. We discretize the domain by using uniform mesh in the time, and piecewise-uniform Shishkin mesh in space. To discretize the spatial derivatives we propose a cubic spline scheme on variable mesh, and apply it on the layer resolving Shishkin mesh. The cubic spline scheme fails to satisfy stability in the outer region. To overcome this difficulty, we use the classical central difference scheme only for the outer region, and the cubic spline scheme for the inner regions. For the discretization of the time derivative we use the Crank-Nickolson scheme and the Extendeded Trapezoidal formula. The newly proposed schemes are of order $O((\triangle t)^3 + (\triangle x)^2)$. The Crank-Nickolson scheme produces nonphysical oscillations near the boundaries when there are inconsistencies in the boundary and the initial conditions. The Extendeded Trapezoidal formula is capable of handling such difficult phenomena. The truncation error, and stability estimates are obtained. The proposed methods are applied to some test problems to verify the theoretical results.

Simulation of a pollution problem in porous media . **Rajae Aboulaich** (LERMA, Ecole Mohammadia d'Ingénieurs, RABAT, Morocco) IC/CT1916/002

When the ground is accidentally or industrially polluted with a volatile organic pollutant, it is very important to know the amount of this contamination in its liquid form. A relevant question for determining a possible remediation senarii is the ability to characterize the level of the pollution in a short time. We are interested in determination of the concentration in liquid phase of a volatile organic pollutant at initial time, since we can compute its concentration in gaseous phase at final time. This leads to solve an inverse problem (see [1]). We study the existence and uniqueness of solutions for the direct problem in bi-dimensional setting extending the previous work done for uni-dimensional problem [1].

By applying finite volumes method, we discretize the problem and we prove some *a priori* and *a posteriori* error estimates under some suitable conditions. Finally, we globally solve the considered problem by using the finite volumes method.

Numerical Method for the KdV–Kawahara and Benney–Lin equations. **Mauricio Sepúlveda** (Universidad de Concepción, Chile), Octavio Vera (Universidad del Bío-Bío, Chile) IC/CT4576/025

We are concerned with the initial-boundary-value problem associated to the Korteweg–de Vries–Kawahara (KdVK) and Benney–Lin equations (BL), which are transport equations perturbed by dispersive terms of 5th order. The (KdVK) and (BL) equations appear in several fluid dynamics problems. We obtain local smoothing effects that are uniform with respect to the size of the interval. We also propose a simple finite-difference scheme for the problem and prove its stability. Finally, we give some numerical examples.

Numerical study of coupled surface and grain boundary motion. **Zhenguo Pan** (University of British Columbia, Canada) IC/CT4583/025

We study the coupled surface and grain boundary motion in a bicrystal in the context of the *quarter loop* geometry. Two types of normal curve velocities are involved in this model: motion by mean curvature and motion by surface diffusion. Three curves meet at a single point where junction conditions are given. A formulation that describes the coupled normal motion of the curves and preserves arc length parametrization up to scaling is proposed. Equations and junction conditions are approximated by finite difference methods. Numerical convergence to exact travelling wave solutions is shown.

Application of discrete variational derivative method. **Daisuke Furihata** (Osaka University, Japan) IC/CT2725/025

We have proposed a method to construct numerical schemes for PDEs which have some dissipative or conservative properties.

This method, we refer to it as discrete variational derivative method(DVDM), is a kind of structure preserving methods for PDEs.

The key idea of DVDM is to discretise the variational structure of PDEs which is essence of those properties using rigorous definitions of discrete variational derivative. It follows that constructed schemes inherit the property of integral functional of PDEs.

For example, we are able to construct dissipative or conservative properties preserving schemes for $\partial u/\partial t = (\partial/\partial x)^{\alpha}(\delta G/\delta u)$, $\partial^2 u/\partial t^2 + C\partial u/\partial t = (\partial/\partial x)^{\alpha}(\delta G/\delta u)$ and other kind of PDEs. Examples of concrete PDEs are Swift-Hohenberg equation, Cahn-Hilliard equation, KdV equation, Camassa-Holm equation and so on.

Due to preserving properties we able to expect that those schemes have preferable properties such as numerical stability and solution uniqueness. In fact, we obtained mathematical proofs for such properties of some our schemes.

Not only applying DVDM to PDEs but we also have studied DVDM carefully to extend it, for instance, to obtain higher order of precision, to use other than finite difference method, to apply higher space dimension and so on. We will talk and indicate result of our effort.

Organiser: James Lambers (Stanford University, USA)

Recent advances in Krylov subspace spectral methods. **James Lambers** (Stanford University, USA) IC/CT806/025

This talk summarizes recent and ongoing work on an alternative approach to the solution of diffusion problems and wave propagation problems in the variable-coefficient case that leads to a new numerical method, called a Krylov subspace spectral method.

The basic idea behind the method, applied to a PDE of the form $\mathrm{d}u/\mathrm{d}t + L(x,D)u = 0$, is to use Gaussian quadrature in the spectral domain to compute Fourier components from elements of $\exp[-L\Delta t]$ for a matrix L discretizing $L(x,D)$ and time step Δt, using algorithms developed by Golub and Meurant, as opposed to applying Gaussian quadrature in the spatial domain as in traditional spectral methods. This strategy allows accurate resolution of all desired components, for both high and low frequencies, without having to resort to smoothing techniques to ensure stability. In fact, by viewing the Fourier components in terms of directional derivatives of moments, we can demonstrate unconditional stability given sufficient smoothness of the coefficients of $L(x,D)$.

We also discuss various generalizations of these methods. We first discuss application to systems, which yields a simple high-order scheme for the second-order wave equation. Next, we consider the use of trial functions other than trigonometric polynomials, including smooth, compactly supported wavelets, and multiwavelet bases similar to those introduced by Alpert *et al.*, with differentiation operators designed to compute moments more accurately in the case of discontinuous coefficients. Numerical results will be presented for both parabolic and hyperbolic problems in one, two and three space dimensions.

This talk includes joint work with Patrick Guidotti and Margot Gerritsen.

A central scheme for shallow-water flows along channels with irregular geometry. **Jorge Balbás** (University of Michigan, Ann Arbor, USA), Smadar Karni (University of Michigan, Ann Arbor, USA) IC/CT3025/025

We present a new high-resolution, non-oscillatory semi-discrete central scheme for one-dimensional shallow water flows along channels with non-uniform rectangular cross sections and bottom topography. The scheme extends an existing central semi-discrete formulation for hyperbolic conservation laws and it enjoys two properties crucial for the accurate simulation of shallow water flows: it preserves the positivity of the water height, and it is well balanced, *i.e.*, the source terms arising from the geometry of the channel are discretized so as to balance the non-linear hyperbolic fluxes –a condition necessary to correctly approximate steady-state solutions. Along with a detailed description of the scheme and its properties, we present several numerical experiments –including the approximation of exact equilibrium solutions– that demonstrate the robustness –and simplicity– of the numerical algorithm.

Numerical solution of the time-dependent incompressible Navier–Stokes equations in the stream function and vorticity formulation. **Fattehallah Ghadi** (Université Ibnou Zohr – Agadir, Morocco), Ruas Vitoriano (Université Pierre et Marie Curie, France), Wakrim Mohamed (Département de Math-Info, Faculté des Sciences. Un, Morocco) IC/CT57/025

In this paper we start by presenting the study carried out for the stationary case, and then we link it to the time-dependent case. In terms of numerical analysis this paper primarily deals with a mixed method to solve the two-dimensional generalized Stokes problem. We introduce a suitable technique based on the splitting of the vorticity into two components. Then we discretize in space the resulting uncoupled system by means of continuous Lagrange finite elements. In computational terms we apply the above technique to the Navier-Stokes equations. This is achieved by first performing the semi-discretization in time of these equations by a classical characteristics method or a semi-implicit integration scheme for the advective term. Then we apply the same numerical ingredients as for the generalized Stokes system. Finally we illustrate the good performance of our approach by means of numerical results, obtained in the framework of some benchmarks.

Lagrange projection scheme for two-phase flows: 2. boundary conditions and second-order enhancement. **Quang Huy Tran** (Institut Français du Pétrole, France), Frederic Coquel (Université Pierre et Marie Curie, France), Quang Long Nguyen (Institut Français du Pétrole, France), Marie Postel (Université Pierre et Marie Curie, France) IC/CT2304/025

We are concerned with the numerical simulation of two-phase flows representing oil transportation along a 1-D pipeline. In the joint contributed talk by Q.L. Nguyen, we have discussed about the motivation and the general philosophy of Lagrange-Euler projection method we propose for this kind of problems. In this presentation, we would like to focus on various technical aspects of utmost importance for numerical analysis, namely:

- The design of appropriate boundary conditions for the implicit-explicit Lagrange-projection scheme. Those boundary conditions are based on Dubois-LeFloch's principle of half-Riemann problems.
- An upper-bound for the time-step ensuring positivity properties. This estimate is closely related to a nice structure of the linear system arising in the Lagrange step.
- The construction of a "genuinely" second-order version of the scheme, inside the computational domain as well as on the boundaries. Our approach lies in seeking corrective factors for the slopes from the equivalent equations of the system.

To our knowledge, the proposed methods answer open problems of both practical and theoretical importance. After providing mathematical details for a simplified case of the physical model, relevant numerical results are shown for academic test cases.

Surface-tension driven flows in microfluidics. **Paul Vigneaux** (Université de Bordeaux, France), Cédric Galusinski (Université du Sud-Toulon-Var, France) IC/CT2367/025

Making the most of surface tension effects, flows of two immiscible fluids in microdevices allow to create emulsions where droplets moves through microchannels networks and are used as microreactors to study very fast chemical kinetics. But a better understanding of hydrodynamics inside droplets is needed in order to achieve flow control needed in practical applications. Simulations of such flows raise several numerical difficulties. For instance, surface tension induces time consuming simulations and implies the use of accurate curvature computation, in particular when topological changes occur. An approach to deal with the first point is proposed in the talk "A new stability condition for surface tension-driven flows" of the Minisymposium "Level-Set methods: fluid applications" organized by Y. Tsai.

In this talk, we focus on the second point : bifluid flows with multiple droplets are considered. We use Level Set techniques to follow fluid interfaces. Small droplets are numerically captured with a small number of cells. Then, relative volume variations are visible for such small droplets, even with an efficient level set method. Here we propose to control the volume of each droplet by numerical mass conservation. This obliges namely to locate each droplet, i.e. each connected component represented as connected region where the level set function is, for instance, negative. The number of connected components can vary along time because of topological changes. We then propose an algorithm to isolate each connected component in order to compute and correct the droplet mass. Other applications follow from this algorithm: we can compute the scalar velocity of each droplet in the flow and accurate computation of the curvature can be achieved when two droplets are close. This allows relevant simulations of droplet collapse when surface tension plays a major role. Simulations are compared to physical experiments and different mixing regimes inside microdroplets are explored.

Locally divergence-preserving schemes of higher order. **Robert Artebrant** (ETH Zürich, Switzerland) IC/CT4585/025

Violation of the divergence constraint on the magnetic flux density in magnetohydrodynamical (MHD) simulations leads to stability problems. It is therefore of great importance to numerically respect this intrinsic constraint. Since the divergence preservation is a local phenomenon inherent in the MHD-system it is appealing to mimic this property numerically by a locally divergence-preserving scheme.

A common numerical technique for simulation of the MHD-system of conservation laws is the finite volume (FV) method. In [SISC 26 2005 pp. 1166] a local procedure to redistribute the numerical fluxes in a FV-scheme so that a discrete divergence operator vanishes was presented. This procedure stabilizes the base scheme and respects the accuracy to the second order level.

The present talk describes a development of the above procedure that complies with the finite volume framework, preserves a fourth order discrete divergence operator locally and retains the accuracy of a generic semi-discrete finite volume scheme up to fourth order. The redistribution of the numerical magnetic field fluxes is formulated in a standard conservative setting making it trivial to implement the divergence-preserving modification in an existing FV-scheme.

Characteristic non-reflecting boundary conditions for multi-dimensional quasi-linear hyperbolic systems. **Takaharu Yaguchi** (University of Tokyo, Japan) IC/CT2217/025

We will talk about an extension of the characteristic nonreflecting boundary condition for multidimensional quasi-linear hyperbolic systems, which is important for the simulations of waves.

In these three decades, a variety of nonreflecting boundary conditions have been proposed. Among them, the characteristic nonreflecting boundary condition is widely used for the simplicity of the implementation, but it has a problem that waves are assumed to propagate perpendicular to the boundaries.

In this talk we provide a method to derive characteristic nonreflecting boundary conditions under a weaker assumption that there exist only simple waves. In our method, the coefficients of the equations describing the characteristic curves are adaptively estimated by applying method of characteristics, and

then, reflections are eliminated by a flux vector splitting technique suitable for our method.
We demonstrate the effectiveness of our method by showing numerical examples for the Euler equations and the Maxwell equations.

Local non-reflecting boundary condition for time-dependent multiple scattering. **Imbo Sim** (Universität Basel, Switzerland), Marcus Grote (Universität Basel, Switzerland) IC/CT2478/025

When an incident wave encounters an obstacle, it is scattered in the unbounded surrounding medium. If two or more obstacles are present, the field scattered from one obstacle will induce further scattered fields from all the other obstacles, which again will induce further scattered fields from all obstacles, and so forth. When the scatterer consists of several obstacles, which are well separated from each other, the use of a single artificial boundary to enclose the entire scattering region becomes too expensive. Instead it is preferable to enclose every sub-scatterer by a seperate artificial boundary. Then, any boundary condition for such *multiple scattering problems* must not only let outgoing waves leave a sub-domain without spurious reflection from its artificial boundary, but also propagate subsequently the outgoing wave to all other sub-domains. In [2,3], Grote and Kirsch derived a nonreflecting boundary condition(NBC) for time-dependent multiple scattering, which is local in time but nonlocal in space. Here, based on high-order *local nonreflecting boundary condition*(LNBC) for single scattering [1], we seek a LNBC for time-dependent multiple scattering, which is completely *local both in space and time*. To do so, we first develop a high order representation formula for a purely outgoing wave field, given its values and those of certain auxiliary functions needed for the LNBC on the artificial boundary. By combining that representation formula with the decomposition of the total scattered field into purely outgoing contributions, we obtain the first exact, completely local, NBC for time-dependent multiple scattering. Remarkably, the information transfer (of time retarded values) between sub-domains will only occur across those parts of the artificial boundary, where outgoing rays intersect neighboring sub-domains, i.e. typically only across a fraction of the artificial boundary. The accuracy, stability and efficiency of this new LNBC is evaluated by coupling it to standard finite element and finite difference methods.

key words: time-dependent waves, local nonreflecting boundary condition, local space, local time, multiple scattering

A new high-order finite-volume method for hyperbolic balance laws. **Bettina Messerschmidt** (Universität Kassel, Germany) IC/CT1435/025

Solving PDEs numerically it is often necessary to use methods that guarantee a high order time resolution, especially when the evolution of a process shall be predicted over a longer period.
The already known ADER approach is a way to obtain solutions with a time order greater than one, more precisely it allows convergence of (at least theoretically) arbitrary high order in time. This technique has the disadvantage that for each integration point solving as many Riemann Problems as the designated order is needed, which causes a certain effort in both programming and computing time.
In this talk a new approach will be presented that needs solving only one Riemann Problem per integration point and is much simpler to implement. This procedure is a derivative of the ADER Scheme and uses Taylor Series not only in time but also in space, so that one gets only one value per integration point and side which leads to only one Riemann Problem. A comprehensive comparison of the mentioned numerical schemes in the background of the Shallow Water Equation, with respect to both accuracy and computational effort, will be presented.

Construction of Galerkin schemes that retain energy dissipation or conservation property. **Takayasu Matsuo** (University of Tokyo, Japan) IC/CT1527/025

In this talk numerical integration of a certain partial differential equations (PDEs) that have energy dissipation or conservation property, such as the nonlinear Schrödinger equation, the Korteweg-de Vries equation, or the Cahn-Hilliard equation, is considered. For such PDEs, numerical schemes that retain the energy dissipation or conservation property ("dissipative" or "conservative scheme") are generally prefered in that they often imply physically better and numerically stabler results. Thus so far many studies to seek for dissipative/conservative schemes have been done in this context. Among them, quite recently an unified approach to find dissipative/conservative Galerkin schemes has been proposed by the present author. In this talk, this approach is first briefly reviewed, and its extension and several new application examples of the approach are discussed.

Algorithm and Matlab package for some nonlinear 2D evolution equations. **Damian Trif** (Universitatea Babeş-Bolyai, Romania) IC/CT1251/025

The paper presents an algorithm and the corresponding MATLAB package to solve some partial differential evolution equations of the form $u_t + Lu = N(u, u_x)$, with boundary and initial conditions, where L is a 2D linear elliptic operator and N is a nonlinear part. The algorithm is based on the eigenfunctions expansion together with the Lyapunov-Schmidt reduction procedure. The eigenfunction basis of the linear part L of the problem is used to represent the solution at every time level and these eigenfunctions are calculated in a preprocessing stage. A boundary-fitted computational grid is generated in order to allow a complex geometry of the physical domain and this also facilitates the use of previous 1D versions LiScEig and LiScNLE of the package (D. Trif, LiScEig Tutorial 2005, LiScNLE Tutorial 2006, http://www.mathworks.com/matlabcentral/fileexchange > Mathematics > Differential Equations > LiScEig 1.0 or LiScNLE 1.0). The advantages of such computations can be remarked in many non-trivial examples. Future extensions to free surface problems or blood flow in microcirculation are also discused.

Local and global time-stepping for fully-adaptive multi-resolution methods to solve evolutionary PDEs. **Margarete Domingues** (Instituto Nacional de Pesquisas Espaciais, Brazil) IC/CT750/025

We present a fully adaptive numerical scheme for evolutionary PDEs based on a finite volume discretization. A multiresolution strategy allows local grid refinement while controlling the approximation error in space. The space implementation uses a dynamic tree data structure which allows memory compression and CPU time reduction. The costly fluxes are evaluated on the adaptive grid only. The explicit time discretization, uses either a local scale dependant time step (LTS) or a global time step control (GTS). For the LTS, the time step for the finest scale is imposed by the stability requirement of the explicit second order Runge–Kutta scheme. The time step on a given scale is subsequently twice lager than the one on the next finer scale. For the GTS, a combination of third and second order Runge-Kutta compact schemes are used to control and ajust the time step. Numerical validations are presented for different test problems, like convection-difussion, Burgers equation and Euler equation. To demostrate the efficiency of the different adaptive schemes, we applied them to a non-linear problem in three space dimensions. The gain in memory and CPU time with respect to the finite volume scheme on a regular grid and the adaptive multiresolution method is reported and demonstrates the efficiency and accuracy of such implementations.

Boundary-element method for spatially-periodic potential problems. **Hidenori Ogata** (The University of Electro-Communications, Japan) IC/CT4340/026

In this study, we propose a boundary element method (BEM) for two-dimensional potential problems with one-dimensional periodicity such as electrostatic problems including an infinite periodic array of electric conductors. The conventional BEM is based on boundary integral equations. It is, however, difficult to solve periodic problems by the conventional BEM because the solution, which includes periodic functions, is difficult to be obtained by solving the integral equation including the Green function due to an isolated source. We propose a BEM based on a "periodic" Green function, a Green function due to a periodic array of sources, which successfully provides approximate solutions of periodic potential problems.

A reduction approach of mixed finite element methods in magnetic fields problems. **Daisuke Tagami** (Kyushu University, Japan) IC/CT3219/026

We are concerned here with finite element computations of magnetic field problems; for example, three-dimensional eddy current problems using the magnetic vector potential as an unknown function. By introducing a mixed formulation with the gauge condition, we can mathematically justify the existence and unique solvability, and the convergence of the approximate solution; for example, see[3] in the magnetostatic case. However, the mixed formulations cause the difficulty to apply iterative solvers to the resultant linear systems. This fact makes one of the main disadvantage in the practical computations for large scale models of electric facilities. On the other hand, a formulation without the gauge condition (hereafter, we call “reduction approach”) is often used, where it is known that the convergence of iterative solvers is improved by taking care of the continuity of an excitation current density; for example, see[1] and[2]. However, in “reduction approach”, the unique solvability is disregarded.

Therefore, in this paper, we focus our attention on mathematical justifications of “reduction approach”, which means to prove the existence and unique solvability, to prove the convergence, and to find the relation between the constraint condition of the mixed problem and “reduction approach”.

Applications of RBF collocation method to elliptic PDEs in an arbitrary domain by fictitious domain extensions. **Jiahn-horng Chen** (National Tiawan Ocean University, Taiwan) IC/CT371/026

It is known that the multiquadric functions possess the best capability in scattered data fitting and their convergence is of exponential order. Recently, the multiquadric radial basis function (RBF) collocation method has been widely applied to solve partial differential equations. The applications are usually restricted to simple domains. However, the geometries of problems in industry and engineering are almost always irregular and complicated. To employ the RBF collocation method to solve a problem in an arbitrary domain, one usually needs to incorporate some domain decomposition techniques in a typical solution procedure. In this way, iterations are required.

In this paper, we introduce a fictitious domain extension approach that extends the arbitrary physical geometries defined in a problem to a topologically rectangular domain. In this approach, the definitions of the solution function and its governing equation are extended to the fictitious region and its boundary. The physical boundary conditions are still specified on the boundaries of the physical domain. And then the RBF collocation method is applied in the new extended domain. Applying this approach to several test problems with arbitrary geometries, we demonstrate that the solution can be directly obtained without domain decompositions and iterations. We also tested the approach for problems with different types of boundary conditions. The results show that the new approach is simple, efficient and accurate.

The composite mini-element: a mixed FEM for the Stokes' equations on complicated domains. **Daniel Peterseim** (Universität Zürich, Switzerland), Stefan Sauter (Universität Zürich, Switzerland) IC/CT3293/026

In this talk, we introduce a new mixed finite element for the discretization of the Stokes equations with Dirichlet as well as slip boundary conditions. The underlying grids of the standard finite element pairs, like the well-known Mini Element, always has to resolve the domain which affects the number of degrees of freedom critically. In contrast to that, our approach decouples the minimal dimension of the approximation space from the domain geometry by using an overlapping two-scale grid. This approach allows low-dimensional approximations even for problems with complicated geometric details. We prove stability and optimal convergence for the proposed nonconforming mixed method.

A complete flux scheme for the stationary advection-diffusion-reaction equation. **Jan ten Thije Boonkkamp** (Technische Universiteit Eindhoven, The Netherlands) IC/CT2415/026

We derive the complete flux scheme for conservation equations of advection-diffusion-reaction type, which can be considered as a generalization of exponential fitting schemes. The advection velocity, diffusion coefficient and source term can be arbitrary smooth functions. In the complete flux scheme, the numerical flux at a cell interface is computed from the complete differential equation, including the source term. This way we get a numerical flux consisting of two parts, i.e., the homogeneous flux, corresponding to the advection-diffusion operator, and the inhomogeneous flux, corresponding to the source term. For two-dimensional problems we include the cross flux in the source term. The numerical flux behaves second order accurate, uniformly in the local Peclet numbers. We have combined the complete flux scheme with the cell-centred finite volume method, and the resulting scheme is second order accurate and not prone to spurious oscillations, even for dominant advection. Moreover, for two-dimensional problems crosswind diffusion is virtually absent. Finally, we have modified the scheme for the spherically symmetric advection-diffusion-reaction equation.

An augmented discontinuous Galerkin method for elliptic problems. **Rommel Bustinza** (Universidad de Concepción, Chile), Tomas Barrios (Universidad Católica de la Santisima Concepción, Chile) IC/CT3097/026

In this work we propose an augmented discontinuous Galerkin method for elliptic linear problems in the plane with mixed boundary conditions. Our approach introduce Galerkin least-squares terms, arising from constitutive and equilibrium equations, which allow us to look for the flux unknown in the local Raviart-Thomas space. The unique solvability is established avoiding the introduction of lifting operators and we derive a Céa estimate, which let us conclude that the rate of convergence of error, measured in an appropriate norm, is optimal respect to the $h-$version. We emphasize that for practical computations, this method reduces the degrees of freedom, with respect to the classical discontinuous Galerkin method. In addition, an aposteriori error analysis is presented and some numerical experiments are included, which validate our theoretical results.

Variable transformations in numerical integration. **Avram Sidi** (Technion – Israel Institute of Technology) IC/CT3991/022

Consider the problem of evaluating finite-range integrals of the form

$$I[f] = \int_0^1 f(x)\,dx,$$

where $f \in C^\infty(0,1)$, but $f(x)$ may behave singularly at the endpoints with different types of singularities. One very effective way of computing $I[f]$ is by first transforming it with a suitable variable transformation and next applying the trapezoidal rule to the resulting transformed integral. Thus, if we make the substitution $x = \psi(t)$, where $\psi(t)$ is an increasing differentiable function on $[0,1]$, such that $\psi(0) = 0$ and $\psi(1) = 1$, then the transformed integral is

$$I[\hat{f}] = \int_0^1 \hat{f}(t)\,dt; \quad \hat{f}(t) = f(\psi(t))\psi'(t).$$

If $\psi(t)$ is chosen such that $\psi^{(i)}(0) = \psi^{(i)}(1) = 0$, $i = 1,2,\ldots,p$, for some sufficiently large p, then the trapezoidal rule applied to $I[\hat{f}]$ produces approximations of surprisingly high accuracy even with a small number of abscissas.

Variable transformations in numerical integration have been used as a means to improve the performance of the trapezoidal rule and of the Gauss–Legendre quadrature for singular one-dimensional integrals. They have also been used in multidimensional integration to "periodize" the integrand in all variables to improve the accuracy of lattice rules.

In this lecture, we give an overview of the subject. We discuss the various transformations, old and new. We present some recent developments that enable one to obtain "optimal" numerical results from some transformations that have power-like behavior at the endpoints.

Fast construction of the Fejér and Clenshaw–Curtis quadrature rules. **Jörg Waldvogel** (ETH Zürich, Switzerland) IC/CT4087/022

We present an elegant algorithm [1] for stably and quickly generating the weights of Fejér's quadrature rules and of the Clenshaw–Curtis rule. The weights for an arbitrary number of nodes are obtained as the discrete Fourier transform of an explicitly defined vector of rational or algebraic numbers. Since these rules have the capability of forming nested families, some of them have gained renewed interest in connection with quadrature over multi-dimensional regions.

[1] Waldvogel, J.; Fast Construction of the Féjer and Clenshaw–Curtis Quadrature Rules. BIT Numerical Mathematics (2006) **46**, pp.195–202.

About some quadrature formulae. **Zlatko Udovičić** (University of Sarajevo, Bosnia and Herzegovina) IC/CT944/022

In paper[1] the authors considered the quadrature formulae of the form:

$$\int_0^{N-1} \phi(x) f(x) \mathrm{d}x \approx \sum_{i=1}^{r} w_i f(d_i - \tau),$$

where $\phi(\cdot)$ is a scaling function supported on the interval $[0, N-1]$, d_i are the points from the diadic scale, while the unknown parameters of this formula are weights w_i and shift τ. To obtain better numercial stability, instead of the standard polynomial base, the authors used Chebyshev polynomials of the first kind. We generalized that idea and developed algorithms for using any other orthogonal polynomials. Some numerical examples are also presented.

[1] W. Sweldens and R. Piessens; Quadrature Formulae and Asymptotic Error Expansions for Wavelet Approximations of Smooth Functions. SIAM J. Num. Anal., vol. 31, nr. 4, (1994) pp.2140–2164.

Quadrature formulae with maximal trigonometric degree of exactness. **Marija Stanić** (Univerzitet u Kragujevcu, Yugoslavia), Gradimir Milovanović (Univerzitet u Nišu, Yugoslavia), Aleksandar Cvetković (Univerzitet u Nišu, Yugoslavia) IC/CT4355/022

In this lecture we consider quadrature formulae of interpolatory-type, with multiple nodes, which have maximal trigonometric degree of exactness. Our approach is based on procedure given by Ghizzeti and Ossicini in [Quadrature Formulae, Academie-Verlag, Berlin, 1970.]. We consider $\sigma-$orthogonal trigonometric polynomials of semi-integer degree, and give numerical method for their construction. Also, some numerical examples are included.

Quadratures with respect to the complex Jacobi weight. **Gradimir Milovanović** (Univerzitet u Nišu, Yugoslavia), Aleksandar Cvetković (Univerzitet u Nišu, Yugoslavia) IC/CT4371/002

We consider quadrature formulae of the form

$$\int_{-1}^{1} f(x)\, w(x)\, \mathrm{d}x = \sum_{k=1}^{n} A_k f(x_k) + R_n(f),$$

where $w(x) = (1-x)^{\alpha}(1+x)^{\beta}$ is the Jacobi weight function with complex parameters α and β, such that their real parts greater than -1. Such type of integrals appear in some problems of theoretical physics (*cf.* I. Mancev, Journal of Computational Methods in Sciences and Engineering **5** (2005), pp.73–89).

We derive Gaussian type of quadratures, as well as some other kind of interpolatory formulas. We discuss questions of construction and convergence for such formulas and give some numerical examples.

Gaussian quadratures using values-of-function derivatives. **Aleksandar Cvetković** (Univerzitet u Nišu, Yugoslavia), Gradimir Milovanović (Univerzitet u Nišu, Yugoslavia) IC/CT4373/022

In this talk we consider quadrature rules of the following type

$$\int p d\mu = \sum_{k=1}^{n} w_k((q(D)D^m)p)(x_k),$$

where q is given polynomial with $q(0) = 1$ and D is the derivative operator. We discuss existence of such quadrature rules exact on the polynomial space $\mathcal{P}^{\lambda}_{2n+m-1}$, where

$$\mathcal{P}_{2n+m-1} = \{p \in \mathcal{P}_{2n+m-1} \mid (D^k p)(\lambda) = 0,\ k = 1, \ldots . m-1\}.$$

Quadrature rules of such type with maximal algebraic degree of exactness are called Gaussian quadrature rules using values of function derivatives.

IC/CTS4628/02: Numerical methods for PDEs: stationary problems.

Organiser: Christos Xenophontos (University of Cyprus)
Co-organiser: Marcus Sarkis (WPI/USA and IMPA/Brazil)

Why finite element discretizations can be factored by triangular hierarchical matrices. **Mario Bebendorf** (Universität Leipzig, Germany) IC/CT4381/026

Although the asymptotic complexity of direct methods for the solution of large sparse finite element systems arising from second-order elliptic partial differential operators is far from being optimal, these methods are often preferred over modern iterative methods. This is mainly due to their robustness. In this talk it is shown that an (approximate) LU decomposition can be computed in the algebra of hierarchical matrices with logarithmic-linear complexity and with the same robustness as the classical LU decomposition.

An important application of low-precision approximants are preconditioners. It will be seen from both, analysis and numerical experiments, that a problem independent number of iterations can be guaranteed.

The approximation by hierarchical matrices relies on a so-called admissibility condition which is a geometric condition on the localisation of the degrees of freedoms associated with the rows and columns of each subblock. Since this condition is only sufficient, we will generalize it to a purely algebraic condition and prove existence of approximants.

BDDC preconditioners for DG discretizations of elliptic problems with discontinuous coefficients. **Marcus Sarkis** (WPI/USA and IMPA/Brazil), Maksymilian Dryja (Warsaw University, Poland), Juan Galvis (IMPA, Brazil) IC/CT2789/026

Discontinuous Galerkin (DG) discretizations are becoming more and more popular for approximating PDEs since they are well suited for dealing with local or patch refinements and regions with complex geometries or with discontinuous coefficients. We consider DG discretizations for a second order elliptic equation with discontinuous coefficients. The domain Ω is defined as a geometrical conforming union of polygonal substructures Ω_i of size $O(H_i)$. Inside each substructure Ω_i, a triangulation $T_{h_i}(\Omega_i)$ with a h_i parameter and a conforming finite element method are introduced. To handle the nonmatching meshes across $\partial\Omega_i$, we consider DG discretizations based on symmetrized interior penalty terms on the $\partial\Omega_i$. In the first part of the talk a summary on apriori error estimates is presented for the case where the coefficients are constant inside the substructures Ω_i and possibly highly discontinuous across $\partial\Omega_i$. In the second part of the talk, we discuss BDDC solvers based on special orthogonal decompositions of the unknown variables. Under natural assumptions among the coefficients and mesh sizes across $\partial\Omega_i$, a condition number estimate $C(1 + \max_i \log^2 \frac{H_i}{h_i})$ for the preconditioned system is established with C independent of h_i, H_i and the jumps of the coefficients. The algorithms are well suited for parallel computation and can be straightforwardly extended to 3-D problems. Numerical experiments are presented.

An alternating direction Galerkin method for some nonlinear problems. **Sum Chow** (Brigham Young University, USA) IC/CT4377/026

Several problems in porous medium flows and glaciology involve the solution of partial differential equations with gradient dependent nonlinearity. The numerical solution of the resulting nonlinear system is rather expensive. In this paper, we present an alternating direction Galerkin method that allows much faster solution of the nonlinear system.

Our approach is fairly general in scope and covers many problems appearing in diverse application areas. The alternating direction formulation help reduce the problem into a sequence of nonlinear systems that may be solved very efficiently. One special feature of the method is that in for the nonlinear system related to each direction, the solution method is closer to a direct solve than an iterative approach. Theoretical study of the convergence of the method will also be presented.

A singular function boundary integral method for elliptic problems with boundary singularities. **Christos Xenophontos** (University of Cyprus) IC/CT1110/002

We consider a singular function boundary integral method for the approximation of two-dimensional Laplacian problems with boundary singularities due either to the geometry of the domain or to changes in the boundary conditions. In this method, the approximation is constructed by truncating the asymptotic expansion for the solution near the singular point and the Dirichlet boundary conditions are weakly enforced by means of Lagrange multiplier functions. The resulting discrete problem is posed and solved on the boundary of the domain, away from the point of singularity, hence the dimension of the problem is reduced by one. In this talk we will present the numerical analysis of the method, and in particular show that the method approximates the generalized stress intensity factors, i.e., the coefficients in the asymptotic expansion, at an exponential rate. Numerical examples illustrating the convergence of the method and its extension to other elliptic problems with singularities will also be presented.

Non-polynomial spline methods for solving a fourth-order parabolic equation. **Arshad Khan** (Jamia Millia Islamia, New Delhi, India) IC/CT4701/026

In this paper a fourth-order parabolic partial differential equation, that governs the behaviour of a vibrating beam, is solved by using a three level method based on non-polynomial quintic spline in space and finite difference discretization in time. Stability analysis of the method has been presented. It is shown that by choosing the parameters suitably most of the methods can be derived from our method. We also obtain two new high accuracy schemes of $O(k^4, h^6)$ and $O(k^4, h^8)$ and two new schemes which are analogues of Jain's formula for the non-homogeneous case. Comparison of our results with some known methods show the superiority of the present approach.

On the projection to a certain convex set in $H_0^1(\Omega)$, II. **Tomoyuki Idogawa** (Shibaura Institute of Technology, Japan) IC/CT2980/061

Let Ω be a bounded domain with a smooth boundary and $K := \{v \in H_0^1(\Omega) \mid \|\nabla v\|_{L^\infty(\Omega)} \leq 1\}$. In a variational treatment of elasto-plastic torsion problem, the projection mapping $P_K : H_0^1(\Omega) \to K$ plays an important role. We had already showed an iteration algorithm to get $P_K u$ for 1-dimensional case $\Omega = (a, b)$, in the ICIAM-99. We will consider higher dimensional cases and will talk about some related topics.

IC/CTS4640/02: Mesh generation, adaptive methods, multigrid.

Organiser: Wael Elleithy (Universität Linz, Austria)
Co-organiser: Andrei Drăgănescu (Univ. Maryland at Baltimore County, USA)

An abstract method for extending two-level preconditioners to multilevel preconditioners of comparable quality. **Andrei Drăgănescu** (Univ. Maryland at Baltimore County, USA) IC/CT2564/027

We present an abstract method for designing a multilevel preconditioner given a two-level preconditioner for an operator with positive definite symmetric part.

If we denote by A_{fine} and A_{coarse} two discrete versions of a continuous operator, then a two-level preconditioner T_{fine} for A_{fine} is generally described by

$$T_{\text{fine}} = \mathcal{F}(A_{\text{coarse}}^{-1}, A_{\text{fine}}) \approx A_{\text{fine}}^{-1}\,, \qquad (1)$$

where it is assumed that the evaluation of $\mathcal{F}$ requires a level-independent number of applications of A_{fine} and k applications of A_{coarse}^{-1} ($k = 1$ or 2). The natural extension to a multilevel preconditioner, consisting in replacing the call to A_{coarse}^{-1} in (1) with a recursive call to $\mathcal{F}$, is known to sometimes produce multilevel preconditioners of lower quality (e.g., for certain types of inverse problems). Based on the idea that inverting A_{fine} essentially means to solve the nonlinear equation $X^{-1} - A_{\text{fine}} = 0$, we define our multigrid preconditioner to be the first Newton iterate of the map $X \mapsto X^{-1} - A_{\text{fine}}$ starting at the "natural" multilevel preconditioner. For $k = 1$, the resulting algorithm has a W-cycle structure, and differs only slightly from the textbook version of the W-cycle. Moreover, the method guarantees that the resulting preconditioner maintains the approximation quality of the initial two-level preconditioner. The quality of approximation is measured using a distance function that measures the degree to which two operators with positive definite symmetric parts are spectrally equivalent. We apply this method to designing and analyzing a multigrid preconditioner for a linear advection-diffusion-reaction equation.

On a stable coupling approach to multiscale simulations. **Konstantin Fackeldey** (Universität Bonn, Germany), Rolf Krause (Universität Bonn, Germany) IC/CT2720/008

We present a stabilized coupling approach for the multiscale simulation of nonlinear processes in mechanics using finite elements and molecular dynamics concurrently. The key idea is to construct a transfer operator between the different scales on the basis of weighted local averaging instead of using point wise taken values. The local weight functions are constructed by assigning a partition of unity to the molecular degrees of freedom. This allows for decomposing the micro scale displacements into a low frequency and a high frequency part by means of a weighted $L2$-projection. As a consequence, spurious modes are eliminated by construction of the transfer operator. Numerical experiments illustrating the stabilizing effect of our coupling approach are given.

Two-level preconditioners for 3D flows in highly-heterogeneous porous media. **Iryna Rybak** (Fraunhofer ITWM, Kaiserslautern, Germany), Richard Ewing (Texas A&M University, USA), Oleg Iliev (Fraunhofer ITWM, Kaiserslautern, Germany), Raytcho Lazarov (Texas A&M University, USA) IC/CT4432/027

The talk concerns two-level DD/MG type preconditioners for 3D pressure equation with highly varying discontinuous scalar and tensor coefficients. Multipoint flux approximation approach is used for finite volume discretization of the boundary value problem. The domain is divided into nonoverlapping subdomains (blocks), and two-level domain decomposition preconditioners are considered. The heterogeneities are not resolved by the coarse blocks boundaries, therefore the choice of the coarse grid operator is a non-trivial task. The choice of the interlevel operators is also critical for the convergence of the method. The coarse scale operator used here is derived via the homogenization approach. Solutions of local auxiliary problems (so called cell problems) are postprocessed in order to upscale the permeability tensor. Different types of boundary conditions for the cell problems are studied. Namely, these are periodic, linear, oscillatory and Neumann boundary conditions. In the case of periodic porous media, all these boundary conditions allow to calculate one and the same upscaled permeability tensor. However, if the medium is not periodic, different boundary conditions for the auxiliary cell problems lead to different block permeability tensors, what in turn may influence the convergence of the two level DD iterative method. This influence is numerically studied on various types of non-periodic porous media. The influence of the oversampling is studied as well. Furthermore, different choices for a smoothing procedure are studied. These are overlapping and non-overlapping Schwarz DD methods as well as ILU. Results from numerical experiments are presented in order to demonstrate the performance of the considered two-level DD preconditioners.

FEM–BEM coupling for elasto-plastic analysis: automatic adaptive generation of the FEM and BEM zones of discretization. **Wael Elleithy** (Universität Linz, Austria), Ulrich Langer (Universität Linz, Austria) IC/CT3404/027

The intention of coupling the finite element method (FEM) and the boundary element method (BEM) is to combine the advantageous properties of both discretization methods.

The theory and algorithms of coupling FEM and BEM solutions reached, by now, a fairly matured state. However, existing FEM-BEM coupling approaches requires *a priori* defined zones of discretization (FEM and BEM sub-domains). Furthermore, the predefined FEM and BEM zones of diecretization do not change during the computation. As a consequence, the plastic zone (finite element zone of discretization) must be manually localized in advance. This requires preliminary expert knowledge about the problem at hand and may limit the general applicability of the coupling method. The computational cost can be higher than necessary depending on the definition of the finite element and boundary element zones of discretization (FEM and BEM sub-domains).

In this work, we present the concept and the implementation issues for an adaptive FEM-BEM coupling method for two-dimensional elasto-plastic analysis. The nonlinearity, e.g., plastic material behavior, is treated by the finite element method while large parts of the finite/infinite linear elastic body are treated using the boundary element method. The FEM sub-domain discretization is progressively adapted and automatically generated to include zones where plasticity occurs, according to the state of computation. The substantial decrease in the size of FEM meshes, plainly leads to reduction of required system resources and gain in efficiency. Moreover, higher accuracy is achieved.

02: Numerical Analysis, Posters

IC/PP388/002: **Optimal long-distance transport systems in nature: control and applications.**

Presenter: Natalya Kizilova (Kharkov Polytechnic University, Ukraine)

Long-distance conducting systems in high plants and animals are presented by networks of either rigid tubes with porous walls (in plants) or distensible tubes with impermeable walls (in animals). Geometrical relations between the diameters, lengths and branching angles of separate conducting vessels have been studied on morphometric data for the intraorgan arterial systems of a human and by computer-assisted image analysis of plant leaf venation [1]. Some results of the comparative analysis are presented. It was shown that the relationships between the geometrical parameters of the transport systems are similar in animals and plants and correspond to the optimal pipelines with impermeable and permeable walls accordingly. The optimization criterion is the total energy expenses W for the liquid delivery and construction of the system. Global optimality at the systemic level is provided by local optimality conditions in each conducting element. The self-similar branching systems with/without anastomoses are considered here as the models of the transport systems in different inner organs of animals and different venation type of the plant leaves. Steady and unsteady flows of a viscous liquid in the systems with permeable/impermeable walls are investigated [2]. Some important features of the conducting systems which are optimal in the meaning of the criterion $W \rightarrow min$ are revealed. It is shown that complexity of the branching system of the optimal tubes leads to certain regularities in the hydraulic and wave properties of the systems. Hydraulic conductivity of the systems with anastomoses is less than the conductivity of the tree-like systems even at the constant total volume of the material that is used for construction of the system. Both hydraulic conductivity and wave admittance of the system decrease when they are considered as functions of the longitudinal coordinate along the branching system. Reflection coefficient G (ratio of the amplitudes of the forward and backward waves) is an increasing function of the longitudinal coordinate in the way that G<0 for the tubes with initial branching orders (n=1-4). That implies that construction and complexity of the biological long-distance transport systems provide relatively low conductivity for the steady liquid flow and negative reflections and active sucking of the liquid for the wave flow through the system. Possible biomedical and technical applications of the revealed regularities are discussed.

IC/PP4295/020: **Numerical stability of inexact saddle-point solvers.**

Presenter: Pavel Jiránek (Czech Academy of Sciences, Czech Republic)
Co-author: Miro Rozložník (Czech Academy of Sciences, Czech Republic)

Non-symmetric saddle-point problems arise in a wide variety of applications in computational science and engineering. The aim of this presentation is to discuss numerical behavior of several nonsymmetric iterative methods applied for solving the saddle point systems via the Schur complement reduction or the null-space projection approach. Krylov subspace methods often produce the iterates which fluctuate rather strongly. Here we address the question whether large intermediate approximate solutions reduce the final accuracy of these two-level (inner-outer) iteration algorithms. We distinguish between three mathematically equivalent back-substitution schemes which lead to a different numerical behavior when applied in finite precision arithmetic. Theoretical results are then illustrated via numerical examples.

IC/PP547/020: Solution of dense linear systems with wavelet preconditioned GMRES.

Presenter: Lilian Villarín Pildaín (Universidad de La Habana, Cuba)

The solution of dense linear systems of Great Dimensions is generally achieved by direct methods as the tringular factorizations. Pro's: They are *exact* in infinite arithmetic. Con's: In a finite arithmetic, they may be unstable and, when N is too big, really expensive. That's why we try to apply iterative (Krilov) methods for solving them, preconditioning whith an incomplete factorization. To obtain the preconditioner P cheaply, we need a sparsity pattern that approximates the original dense matrix, and that's why we use compression by wavelet bases.

IC/PP4306/021: Deficient discrete C^1 quartic spline interpolation.

Presenter: Pushpraj Choudhary (Govt. Science College, Jabalpur, India)

A discrete spline of certain degree is a piecewise polynomial function of same degree with smoothness at mesh point being expressed in terms of differences rather than continuity of the derivative by Lyche (BIT, 16 (1976), 281-290). Discrete spline has been introduce by Mangasarian and Schumaker (SIAM. J. Conntrol, 9(1971), 174-183) in connection with the solution of certain minimization problem involving differences. Existence uniqueness and convergence properties of discrete cubic spine interpolating a given function at one intermediate point between the successive mesh points are studied by Rana (Proc. of the Japan Acad., 66(1990), 84-88), Dikshit and Rana (Rocky Mountain J. of Math, 17(1987), 709-718) which extend the result of Dikshit and Power (Numer, MAth., 40(1882), 71-78) for discrete cubic spline interpolation. Rana and Dubey (J. Approx.-Theory, 86(1996), 120-127) have obtained assymptotically precise of the difference between the discrete cubic spline interpolation and the function interpolate, which is some times used to smooth histrogram. It has been observed that the deficient spline are more applicable than usable spline as they require less continuity requirement at the mesh points.

In the present paper, we have studied the existence uniqueness and error estimate of deficient discrete C^1-quartic spline interpolation which match the given function values at three intermediate points between the successive mesh point along with two appropriate boundary conditions which are the preferable some to achieve higher accuracy than lower degree splines in which more data are required.

IC/PP4718/021: Multi-frame image super-resolution using self-examples.

Presenter: Mehran Ebrahimi (University of Waterloo, Canada)
Co-author: Edward Vrscay (University of Waterloo, Canada)

We propose a novel multi-frame super-resolution algorithm using our so called *self-examples'*.

The problem of recovering a high-resolution image from a set of distorted (e.g., warped, blurred, noisy) and lower resolution images is known as super-resolution. It is well known that super-resolution is an ill-posed inverse problem, and the effort of the researchers in the past two decades has been mostly focused on defining more efficient regularization expressions to address this ill-posed inverse problem. Furthermore, accuracy of the existing motion estimation algorithms, commonly required in super-resolution algorithms, is always a bounding limit. In 2005, Buades et. al, proposed a novel denoising technique (known as NL-means) for image sequences which does not require motion estimation by taking advantage of the fact that many pixels in the neighboring frames are similar to the current pixel one wishes to denoise. Furthermore, a new class of example-based super-resolution techniques has been very promising in the past few years. However, an external database of examples is typically required for these example-based techniques prior to reconstruction step.

In our super-resolution method, similar to the NL-means multi-frame denoising, no motion-estimation is required. We perform regularization by taking patches from the image sequence itself. However, as opposed to the NL-means multi-frame denoising, patches are taken at different scales, and not at the same scale, allowing us to perform super-resolution.

IC/PP3046/023: An explicit/implicit Galerkin domain-decomposition procedures for parabolic integro-differential equations.

Presenter: Debasish Pradhan (IIT Bombay, India)
Co-author: Neela Nataraj (IIT Bombay, India)
Co-author: Amiya Pani (IIT Bombay, India)

Variational methods are presented for solving approximately a parabolic integro-differential equation that has elliptic part of order $2m$. In this paper, a non-iterative domain decomposition procedure for parabolic integro-differential equation is discussed. The purpose of this paper is to provide the numerical methods for solving the parabolic integro-differential equations by non-overlapping domain decomposition type techniques, introduced by Dawson.

Based on an implicit Galerkin procedures we are solving inside the sub-domains and explicitly calculate the flux value at the interface (i.e., inter-domain boundaries). *A priori error* estimates are derived and the result of a numerical experiment is presented.

IC/PP780/024: Fast and accurate integration of enzyme kinetics equations.

Presenter: Bruno Bieth (Purdue University, USA)
Co-author: Raymond Chin (Indiana University & Purdue University, USA)
Co-author: Lang Li (Indiana University, USA)

Enzyme kinetics equations have positive solutions with multi-scale structure. To solve these equations accurately and efficiently, we developed two fast integration methods in contrast to existing stiff-ODE solvers. Both methods employ an equivalent system of nonlinear Volterra integral equations so derived by using quasi-linearization and by incorporating initial conditions into the equations. This formulation ensures that the solution is always positive. The difference between these two methods lies in the solution procedure. In one, we use orthogonal polynomial associated to an exponential weight, $e^{-\beta t}$ and while in the other we use successive approximation. In this poster session, we report computations using MAPLE of these methods for the enzyme kinetic equations and their errors compared to standard stiff solvers.

IC/PP2596/024: Software library of Taylor series for differential equation.

Presenter: Hiroshi Hirayama (Kanagawa Institute of Technology, Japan)

The arithmetic operations and functions of the Taylor series can be defined by Fortran, C++ and C# language easily. The functions represented by this language can be expanded in the Taylor series. The solution of the differential equations (DE) can also be expanded in the Taylor series.

The software library of Taylor series is developed for the differential equation (DE). The inverse function of $f(x)$ is satisfy the following equation.

$$\frac{dy}{dx} = \frac{1}{\frac{df(y)}{dy}}$$

Using above, the inverse function can easily be expanded in the Taylor series. Therefore we can expand many kinds of function in the Taylor series.

For examples, the solution of the following differential eqaution

$$\frac{dy}{dx} = -\frac{1}{3}x^2y^2, \quad y(2) = 1$$

can be developed in the Taylor series. The first 10 terms of this Taylor series is as follows.

$$\begin{aligned} y(x) \quad &= 1 - 1.33333 * (x-2) + 1.11111 * (x-2)^2 - 0.703704 * (x-2)^3 \\ &+0.345679 * (x-2)^4 - 0.115226 * (x-2)^5 + 0.00137174 * (x-2)^6 \\ &+0.0365798 * (x-2)^7 - 0.0368846 * (x-2)^8 + 0.0246406 * (x-2)^9 \end{aligned}$$

IC/PP1049/024: A high-order energy-conserving integrator.

Presenter: Yuji Ishimori (Toyama Prefectural University, Japan)

We present a numerical integration scheme for the equations of motion

$$\frac{dp_i}{dt} = -\frac{\partial H}{\partial q_i}, \quad \frac{dq_i}{dt} = \frac{\partial H}{\partial p_i} \quad (i = 1, \cdots, d)$$

with the Hamiltonian $H = H(p_1, \cdots, p_d, q_1, \cdots, q_d)$. The enerygy-conserving scheme of order $2n$ is given by

$$p_i^{k+1} = p_i^k - \sum_{j=1}^{n} c_j \sum_{m=1}^{s_j} I_{Q_{ij}}^{\frac{m}{s_j}, \frac{m-1}{s_j}}, \quad q_i^{k+1} = q_i^k + \sum_{j=1}^{n} c_j \sum_{m=1}^{s_j} I_{P_{ij}}^{\frac{m}{s_j}, \frac{m-1}{s_j}}$$

$$P_{ij}^{k+\frac{m}{s_j}} = \frac{s_j - m}{s_j}(p_i^k - \sum_{l=1}^{m} I_{Q_{ij}}^{\frac{l}{s_j}, \frac{l-1}{s_j}}) + \frac{m}{s_j}(p_i^{k+1} + \sum_{l=m+1}^{s_j} I_{Q_{ij}}^{\frac{l}{s_j}, \frac{l-1}{s_j}})$$

$$Q_{ij}^{k+\frac{m}{s_j}} = \frac{s_j - m}{s_j}(q_i^k + \sum_{l=1}^{m} I_{P_{ij}}^{\frac{l}{s_j}, \frac{l-1}{s_j}}) + \frac{m}{s_j}(q_i^{k+1} - \sum_{l=m+1}^{s_j} I_{P_{ij}}^{\frac{l}{s_j}, \frac{l-1}{s_j}})$$

$$P_{ij}^k = p_i^k, \quad Q_{ij}^k = q_i^k, \quad P_{ij}^{k+1} = p_i^{k+1}, \quad Q_{ij}^{k+1} = q_i^{k+1}$$

$$(k = 0, 1, 2, \cdots; i = 1, \cdots, d; j = 1, \cdots, n; m = 1, \cdots, s_j - 1)$$

where $s_1, \cdots, s_n$ are arbitrary positive integers satisfying the condition

$$s_1 < s_2 < \cdots < s_n,$$

$c_1, \cdots, c_n$ are the weights given by

$$c_j = \frac{s_j^{2n-2}}{\prod_{\substack{l=1 \\ (l \neq j)}}^{n} (s_j^2 - s_l^2)} \quad (j = 1, \cdots, n; n \geq 2)$$

and $I_{P_{ij}}^{a,b}$, $I_{Q_{ij}}^{a,b}$ are the 2nd-order approximations of integrals, which are expressed as

$$I_{P_{ij}}^{a,b} = (a-b)\Delta t \delta_{P_{ij}}^{a,b} \overline{\mu}_{P_{ij}}^{a,b} H_j^k, \quad I_{Q_{ij}}^{a,b} = (a-b)\Delta t \delta_{Q_{ij}}^{a,b} \overline{\mu}_{Q_{ij}}^{a,b} H_j^k$$

$$H_j^k = H(P_{1j}^k, \cdots, P_{dj}^k, Q_{1j}^k, \cdots, Q_{dj}^k)$$

The notations δ and $\overline{\mu}$ denote difference quotient and mean difference operators.

IC/PP3042/025: A mortar finite elements for parabolic problems.

Presenter: Ajit Patel (IIT Bombay, India)
Co-author: Amiya Pani (IIT Bombay, India)
Co-author: Neela Nataraj (IIT Bombay, India)

In this paper, a mortar finite element method is used to discretize the space variable, a finite difference scheme is used for time discretization of the parabolic initial and boundary value problems. Optimal error estimates in L^2- and H^1-norms for both semidiscrete and fully discrete schemes are discussed. Numerical experiments are conducted to support the theoretical results.

IC/PP4343/025: Numerical simulation of dislocation dynamics.

Presenter: Petr Pauš (Czech Technical University, Prague, Czech Republic)

Dislocation dynamics is described by the mean curvature flow $v_\Gamma = -\kappa_\Gamma + F$. This law is treated uaing a parametric description. This evolution law is numerically solved by means of either the method of lines or an implicit scheme. Several numerical studies were performed in order to investigate properties of the above mentioned schemes, namely numerical convergence. Additionally we present several qualitative numerical computations showing behavior of dislocations under external stress field.

IC/PP3388/026: Numerical method for elliptic multiscale problems.

Presenter: Isabelle Greff (Universite de Pau et des Pays de l'Adour, France)

A large class of multiscale problems are described by partial differential equations with highly oscillatory coefficients. Such coefficients represent the properties of a composite material or the heterogeneity of the medium in the computation of flow in porous media problem. The computation of an accurate discrete solution of such problems requires a very fine discretisation associated with a fine grid $\mathcal{T}_h$. For such a fine resolution, the storage and computation costs are very high. From an engineer's perspective, we are interested in the average behaviour of the elliptic oscillatory operator on a coarse scale taking into account the small scale features without fully resolving them. We intend to provide a smoother elliptic operator which on a coarse mesh behaves like the original operator.

As a model problem, let us consider the elliptic boundary value problem on Ω, a bounded Lipschitz domain in $\mathbb{R}^d$, $Lu = f$ in Ω and $u = 0$ on $\partial\Omega$, with the right-hand side f in $L^2(\Omega)$. As an example, let

$$L = -\sum_{i,j=1}^{d} \frac{\partial}{\partial_j} \alpha_{ij} \frac{\partial}{\partial_i},$$

whose coefficients may be non-smooth; e.g., $\alpha_{ij} \in L^\infty(\Omega)$ is an oscillatory or jumping coefficient. We require certain real numbers $\underline{\lambda}, \overline{\lambda} > 0$ such that the matrix function $\alpha(x) = (\alpha_{ij})_{i,j=1,\dots,d}$ satisfies $0 < \underline{\lambda} \leq \lambda(\alpha(x)) \leq \overline{\lambda}$ for all eigenvalues $\lambda(\alpha(x))$ of $\alpha(x)$ and almost all $x \in \Omega$. Note that there is no requirement on smoothness or periodicity of the coefficients. Our goal is to construct an elliptic operator A with slowly varying coefficients which behaves similarly to the operator L on a coarse grid. To build A, we will consider the prolongation and restriction operators issued from the multi-grid method framework, and combine them with L. In the case of a T-periodic coefficient α, the homogenisation theory should provide a good operator [1]. To simplify the theory and the numerical implementations, we restrict ourselves to the one-dimensional case. Numerical results for different types of coefficient α (periodic or not) demonstrate the choice of the operator A we built.

This is joint work with Prof. Wolfgang Hackbusch (MPI, Leipzig).

IC/PP739/026: The finite-element method on domains with conical or angular points.

Presenter: Hengguang Li (Department of Mathematics, the Pennsylvania State, USA)

Let Ω be either a polygonal domian in 2-D or a polyhedron in 3-D. Consider the Poisson's equation on Ω with the Dirichlet boundary condition: $-\Delta u = f$ in Ω, $u|_{\partial\Omega} = 0$. We shall show the well-posedness and regularity results for the solution u in some weighted Sobolev space $K_a^m(\Omega)$. In particular, we claim that there is no loss of K_a^m-regularity for the solution of the equation. We then provide an explicit construction of a sequence of finite dimensional subspaces V_n for the finite element method, such that the optimal convergence rate is attained for $u_n \in V_n$, i.e., $||u - u_n||_{H^1(\Omega)} \leq C\dim(V_n)^{-\frac{m}{2}}||f||_{H^{m-1}(\Omega)}$, with C independent of f and n. To be more precise, special meshes for vertices of a polygon or a polyhedron, and the meshes for edges of a polyhedron will be designed to overcome the pollution effects from the sigularities of the solution in the finite element method. Numerical results will be shown to verify our theoretical prediction. This method can extend to more general elliptic equations on domains with conical or angular points.

IC/PP4705/027: Error control in approximation of PDEs via topological gradient and hierarchical error estimator.

Presenter: Zoubida Mghazli (Université Ibn Tofail – Kenitra, Morocco)
Co-author: Abdellah Alla (Université Ibn Tofail – Kenitra, Morocco)
Co-author: Mohamed Masmoudi (Université Paul Sabatier Toulouse III, France)

The mesh adaptation is now an indispensable tool in engineering and simulation. The *a posteriori* error estimates and their use for mesh adaptation have become one of the principal axes of development in the numerical analysis of partial differential equations (PDE). The early a posteriori error estimates has been developed by I. Bubuska and W.C. Rheinboldt in 1978, and a large spectrum of this type of estimates has been devised, essentially for the Finite Element Methods (FEM) of elliptic problems. The main result consists of exhibiting local error indicators which can be computed explicitly as a function of the discrete solution and the data.

Within the FEM, various strategies of a posteriori error estimation have been derived during the last decades. The hierarchical methods are based on a simple idea: given an approximation of order k, a better approximation of order $k+1$ could be used to assess the accuracy of the solution. One only computes the defect-correction in higher order finite element. This gives, in the energy norm, global *a posteriori* error estimation on the solution of the PDE.

The aim of this presentation is to derive a method to control the error in an integral output functional of interest by using an adjoint-based hierarchical error estimation and mesh adaptation. Our approach is based on computing, via the asymptotic expansion, the topological gradient of an auxiliary functional depending on the primal and the dual hierarchical error estimator of the solution of PDE. We prove that this functional is equivalence to the error in functional of interest. The topological gradient is used as a criterion in the strategy of adaptation. Some numerical experiments, will be presented

03: Nonlinear Analysis and Dynamical Systems, Minisymposia

IC/MP270/015: Computational topology and dynamics.

Organiser: William Kalies (Florida Atlantic University, USA)
Co-organiser: Thomas Wanner (George Mason University, USA)

In recent years, computational topological methods have spurred the development of a class of numerical techniques for the rigorous, qualitative analysis of dynamical systems. These methods can provide rigorous verification for the continuation of equilibria, the detection of uniform hyperbolicity, the global decomposition of dynamical systems, and the existence of low dimensional dynamical structures such as fixed points, periodic orbits, connecting orbits, and chaotic dynamics. These methods have been applied to continuous maps such as the infinite-dimensional Kot–Schaffer map, the Swift–Hohenberg and Cahn–Hilliard partial differential equations, and other maps and differential equations. Central to these techniques are the Conley index and computational topology, in particular homology. Computational homology algorithms have also been used to study the dynamics of patterns generated by partial differential equations directly. These techniques have been applied to spinodal decomposition and coarsening in the Cahn–Hilliard equation and to characterize spatial-temporal chaotic behavior in the FitzHugh–Nagumo equations and experimental data of Rayleigh–Benard convection. This minisymposium covers a broad spectrum of computational topological methods including their implementation and their application to the study of dynamical systems.

Algorithms for symbolic dynamics and entropy bounds. **Sarah Day** (College of William and Mary, USA), Rafael Frongillo (Cornell University, USA), Rodrigo Trevino (University of Texas at Austin, USA) IC/MT1634/015

With recent advances in computing power, numerical studies of nonlinear dynamical systems have become increasing more popular. However, errors inherent to such studies may obscure the dynamics or, in the very least, raise doubts about the existence of numerically observed structures. Furthermore, unstable behavior, an intrinsic element of complicated systems, may be difficult to track even with very careful numerical work. I will discuss topological techniques which allow for the rigorous detection of dynamical structures of various stability types. In particular, I will focus on recent work on expanding these techniques that led to the computation of a rigorous lower bound on the topological entropy (one measurement of complexity) for the (chaotic) Henon map.

Computational aspects of Morse decompositions via algebraic lattices. **Robert Vandervorst** (Vrije Universiteit Amsterdam, The Netherlands), William Kalies (Florida Atlantic University, USA) IC/MT3073/015

We discuss the link between basic algebraic structures such as distributive lattices and Morse decompositions. Lattice theory provides simple algorithmic proofs for finding index filtrations and Lyapunov functions.

Computational approach to the Misiurewicz–Mañé theorem. **Hiroshi Kokubu** (Kyoto University, Japan) IC/MT2593/015

Uniform expansion outside a neighborhood of critical points of an interval map, which is known as the Misiurewicz and Mañé's theorem, is a crucial property for the study of one-dimensional dynamics. We shall discuss how this can be obtained, in the case of the quadratic maps, by a rigorous computational method using some graph algorithms. This work is done in collaboration with Sarah Day, Stefano Luzzatto, Konstantin Mischaikow, Hiroe Oka and Pawel Pilarczyk.

Building a data-base for the global dynamics of multi-parameter systems. **Konstantin Mischaikow** (Rutgers University, USA) IC/MT1635/015

It is well accepted that nonlinear dynamical systems can exhibit a wide variety of complex dynamics that may be sensitive to changes in parameters. It is also quite common in applications that not all values of the parameters have been determined. We outline a proposed method for building a data base that can be queried to determine parameter values at which particular types of dynamical structures can be found or values at which specific types of bifurcations occur. The fundamental idea is to use topological methods that are computationally efficient to store essential features of the dynamics in terms of a directed graph with equivalence classes of homology maps at the nodes. The directed graph represents information about the existence of a global Lyapunov function and the homology maps at the nodes encode information about the recurrent dynamics.

We explain these ideas in the context of a density dependent Leslie model arising from population biology.

IC/MP270/015: Computational topology and dynamics. #2

Co-organiser: Thomas Wanner (George Mason University, USA)

(For abstract, see session #1 above.)

Homology algorithms and applications. **Marian Mrozek** (Jagiellonian University, Poland) IC/MT1193/015

Classical homology algorithms, based on the Smith diagonalization algorithm, are supercubical and therefore their applicability is very limited. We present some new ideas for homology algorithms based on one space homology theory and coreduction methods. The ideas lead to fast algorithms for cubical and simplicial homology and homology of maps. Working implementations of these algorithms will be presented and compared with other available algorithms. In the second part of the talk some applications to rigorous numerics of dynamical systems and differential equations as well as medical image analysis will be presented.

Uncertainty quantification for homology computations. **Thomas Wanner** (George Mason University, USA) IC/MT4963/015

Many partial differential equation models arising in applications generate complex time-evolving patterns which are hard to quantify due to the lack of any underlying regular structure. Such models may include some element of stochasticity which leads to variations in the detail structure of the patterns and forces one to concentrate on rougher common geometric features. In many of these instances, such as for example in phase-field type models in materials science, one is interested

in the geometry of sublevel sets of a function in terms of their topology, in particular, their homology.

Recent computational advances make it possible to compute the homology of discrete structures efficiently and fast. Such methods can be applied to the above situation if the sublevel sets of interest are approximated using an underlying discretization of the considered partial differential equation. Yet, this method immediately raises the question of the accuracy of the resulting homology computation.

In this talk, I will present a probabilistic approach which gives insight into the suitability of the above method in the context of random fields. We will obtain explicit probability estimates for the correctness of the homology computations, which in turn yield a-priori bounds for the suitability of certain grid sizes. In addition, we present a computational approach to homology validation in the above setting, and apply our results to certain stochastic partial differential equations arising in materials science.

Rigorous continuation of equilibria of PDEs defined on rectangular spatial domains. **Jean-Philippe Lessard** (Georgia Institute of Technology, USA), Sarah Day (College of William and Mary, USA), Marcio Gameiro (Rutgers University, USA), Konstantin Mischaikow (Rutgers University, USA) IC/MT1628/015

One of the most efficient methods for determining the equilibria of a continuous parameterized family of differential equations is to use predictor-corrector continuation techniques. In the case of partial differential equations this procedure must be applied to some finite dimensional approximation which of course raises the question of the validity of the output. We introduce a new technique that combines the information obtained from the predictor-corrector steps with ideas from rigorous computations and verifies that the numerically produced equilibrium for the finite dimensional system can be used to explicitly define a set which contains a unique equilibrium for the infinite dimensional partial differential equation. In this talk, we'll discuss about some work in progress regarding the above method applied on nonlinear PDEs defined on 2 dimensional rectangular domains.

Hyperbolicity, stability and monodromy of dynamical systems. **Zin Arai** (Kyoto University, Japan) IC/MT2608/015

In this talk, we propose a rigorous computational method for proving uniform hyperbolicity of given dynamical systems.

In general, the uniform hyperbolicity of the chain recurrent set implies the structural stability of the chain recurrent set, and then the structural stability enables us to construct a monodromy homomorphism from the fundamental group of the set of hyperbolic parameter values to the automorphism group of the symbolic dynamics that describes the chain recurrent set of the given system. By computing the monodromy homomorphism, we can reveal the structure of the parameter space of the given dynamical system.

We also present examples of application of the method which include real and complex Hénon maps, and the nonlinear Leslie population model.

IC/MP52/033: On fractional calculus and its applications.

Organiser: Mokhtar Kirane (Université de La Rochelle, France)
Co-organiser: Juan Trujillo (Universidad de La Laguna, Spain)

During the last years, fractional differential equations have assumed an important role in modelling the anomalous dynamics of numerous processes related to complex systems in a large number of diverse areas of science and engineering: Physical Chemistry (sub- and super-diffusion), Geophysics, Materials Theory, Financial Engineering (fractional Black–Scholes Equations), Biology, Signal Processing, Fractional Motion Control, Plasma Physics, etc. This minisymposium is intended to offer some selected methods applied to some representative equations/systems. The presented topics include: nonlinear reaction diffusion equations with fractional powers of the Laplacian, nonlinear diffusion, equations with time fractional derivatives, wave equations with damping of fractional order, fractal equations in quantum mechanics, fractal Burgers' equation, numerical analysis of fractional differential equations.

Activities: a round table on this emergent field will be organized. Future research directions will be discussed.

Fractional equations from fractional variations. **Vasily Tarasov** (Moscow State University, Russian Federation) IC/MT372/033

Fractional generalization of an exterior derivative for calculus of variations is defined. Fractional equations of motion are obtained by fractional variation of Lagrangian and Hamiltonian that have only integer derivatives. Fractional generalization of Hamiltonian and gradient systems are considered by using differential forms and exterior derivatives of noninteger orders.

Fractional variational principles and their applications. **Dumitru Baleanu** (Cankaya Universitesi, Turkey) IC/MT380/033

Variational calculus and Fractional Calculus have played a significant role in various areas of applied sciences such as, among others, Physics, Engineering and Economics. This topic is deeply connected to the very recent developments in theoretical aspects and especially in the numerical schemes of fractional differential equations. In the first part of my talk the fractional Lagrangian formalisms are analyzed, whereas in the second part the fractional Hamiltonian formalisms are discussed. I will expose in this talk the fractional generalization of the traditional variational principles to the constrained systems for both discrete and continuous cases. Also I will present several illustrative examples of fractional Euler-Lagrange and Hamilton equations admitting both analytical and numerical solutions.

Fractional differential equations: interpretations of fractional-order operators and initial conditions in terms of fractional derivatives. **Igor Podlubny** (Kosice, Slovakia) IC/MT377/033

Fractional integration and fractional differentiation are generalisations of notions of integer-order integration and differentiation, and include n-th derivatives and n-folded integrals (n denotes an integer number) as particular cases. Because of this, it would be ideal to have such physical and geometric interpretations of fractional-order operators, which will provide also a link to known classical interpretations of integer-order differentiation and integration.

For proper use in applications, having some interpretations only for fractional order operators is not sufficient. Indeed, there is also a need to understand the meaning of initial conditions for fractional differential equations. Such initial conditions, in general, are expressed as limit values of fractional derivatives and/or integrals.

In our presentation based on our recent investigations we will present interpretations for the fractional order operators and

for the initial conditions expressed in terms of such operators.

First, we will discuss and illustrate several approaches to geometric and physical interpretations of fractional order operators, which appear in fractional differential equations. Then we will demonstrate that it is possible to attribute physical meaning to initial conditions expressed in terms of Riemann-Liouville fractional derivatives, and that it is possible to obtain initial values for such initial conditions by appropriate measurements or observations.

Fractal Hamilton–Jacobi–KPZ equations. **Wojbor Woyczynski** (Case Western Reserve University, USA) IC/MT381/033

Nonlinear and non-local evolution equations of the form $u_t = Lu \pm |\nabla u|^q$, where L is a pseudo-differential operator representing the infinitesimal generator of a Lévy stochastic process, have been derived as models for growing interfaces in the case when the continuous Brownian diffusion surface transport is augmented by a random hopping mechanism. The goal of this paper is to study properties of solutions to this equation resulting from the interplay between the strengths of the *diffusive* linear and *hyperbolic* nonlinear terms, posed in the whole space $\mathbb{R}^N$, and supplemented with non-negative, bounded, and sufficiently regular initial conditions.

This is joint work with Greg Karch.

On the fractional telegraph problem. **Nasser eddine Tatar** (King Fahd University, Saudi Arabia) IC/MT402/033

In this talk we shall be concerned with the fractional telegraph problem. This problem arises while studying some iterated Brownian motions. The equation involved can be looked at as a generalization of the weakly internally damped wave equation. The first (corresponding to the weak internal damping) and the second order temporal derivatives are replaced by fractional derivatives. The questions of well-posedness, stability and blow up in finite time will be addressed. Some new methods and techniques will be presented. Moreover, several interesting special cases will be highlighted.

Finite-time blow-up and life span of a non-automomous semilinear equation. **Aroldo Perez-Perez** (Universidad Juárez Autónoma de Tabasco, Mexico) IC/MT400/033

Consider the semilinear nonautonomous equation $\frac{\partial}{\partial t}u(t) = k(t)\Delta_\alpha u(t) + u^{1+\beta}(t)$ with $u(0,x) = \lambda\varphi(x)$, $x \in \mathbb{R}^d$, where $\Delta_\alpha := -(-\Delta)^{\alpha/2}$, $0 < \alpha \le 2$, $\lambda, \beta > 0$ are constants, $\varphi \ge 0$ is bounded, continuous and does not identically vanish, and $k : [0,\infty) \to [0,\infty)$ is a locally integrable function satisfying $\varepsilon_1 t^\rho \le \int_0^t k(r)\,dr \le \varepsilon_2 t^\rho$ for all t large enough, where $\varepsilon_1, \varepsilon_2, \rho > 0$ are given constants. We prove that any constellation of positive parameters d, α, ρ, β, obeying $0 < d\rho\beta/\alpha < 1$, yields finite time blow up of any nontrivial positive solution. Under suitable additional assumptions, we also obtain upper and lower bounds for the life span $T_{\lambda\varphi}$ of the above equation, which prove that $T_{\lambda\varphi} \sim \lambda^{-\frac{\alpha\beta}{\alpha - d\rho\beta}}$ near zero. "Work done in collaboration with Kolkovska, E.T. and López-Mimbela, J.A".

Diffusion-wave and relaxation problem. **Mirjana Stojanovic** (Univerzitet u Novum Sadu, Yugoslavia) IC/MT383/033

By the notion of fractional derivative of distributed order we consider the time fractional equation of distributed order

$$\int_0^2 p(\beta)[D_*^\beta u(t,\cdot)]d\beta = \rho^2 \frac{\partial^2}{\partial x^2}u(t,\cdot),\ p(\beta) > 0, \qquad (1)$$

where $p(\beta)$ is the weighted function, $x \in \mathbf{R}$, $t \ge 0$, subject to the initial data $u(0^+,\cdot) = \varphi(\cdot)$, $u_t(0^+,\cdot) = \psi(\cdot)$, D^β concerns the Caputo derivative.

As method for construction of the solution we use in sequence Fourier and Laplace transform and their inverse.

We prove the existence-uniqueness of the solution and regularity of the solution in the space $C^\infty(\mathbf{R})$, (w.r.) to the spatial variable, when the initial data are L^2-functions. We find upper viscosity solutions.

We generalize result to two-term, three-term and finally n-term equation.

This equation have an application in visco-elasticity and in anomalous diffusion processes.

Concerning the investigation of the diffusion-wave problem, we conclude the following: for $\beta = 1$ we have heat equation which smooths all the rough, singular initial data. For $\beta = 2$ we have wave equation which propagate singularities of the initial data. Diffusion-wave equation ($0 < \beta < 2$,) gives as a solution C^∞-function (w.r.) to the spatial variable x if the initial data are bounded in L^2-norm. Thus, the operator of the diffusion-wave equation have more properties of heat operator. It smoothes initial data, but requires their boundedeness in L^2-norm.

We consider fractional relaxation equation of distributed order in interval $(0,2)$ using Caputo derivatives approach:

$$\int_0^2 p(\beta)D_*^\beta u_*(t)dt = -\lambda u_*(t) \qquad (2)$$

subject to he initial data $u(0_*^+) = 1$, where $p(\beta) \ge 0$, $\int_0^1 p(\beta) = P > 0$. Constant P can be normalized to 1, $*$ is the sign for Caputo derivative.

We find exact solution using different weighted functions giving solutions in intervals $(1,2)$ and $(0,2)$. We give the qualitative analysis of the solutions, their asymptotic behavior at zero and infinity. For behavior between the extremals we use integral representation of the solution and prove the oscillatory character finding the number of zeros of the solution in interval $t \in [0,\infty)$.

The solution of the relaxation equation on interval $(0,2)$ inherits the asymptotic behavior of the solution on the interval $(0,1)$. In the interval $(0,1)$ the solution have the relaxation properties, tends to zero as $t \to \infty$, while in the interval $(0,2)$ the solution oscillate.

Adaptive quadratures and fractional IDEs: applications in image processing. **Eduardo Cuesta** (Universidad de Valladolid, Spain) IC/MT364/033

In this work we consider partial integro-differential equations of fractional order whose prototype is

$$(1)\quad u(t,x,y) = u_0 + \int_0^t \frac{(t-s)^{\alpha-1}}{\Gamma(\alpha)}\Delta u(s,x,y)\,ds + f(t,x,y), \quad (t,x,y) \in [0,T]$$

where $1 < \alpha < 2$, $\Omega \subset \mathbb{R}^2$ and Δ stands for the 2-D Laplacian.

Numerical schemes to approximate the solution of (1) have been widely studied in literature, in particular the ones based on fractional convolution quadratures. However, the high com-

putational cost of these methods made its use in practical applications unaffordable the most of times. Therefore, it is not surprising that the effort of many authors concentrates at present not only in finding higher order numerical methods but in obtaining faster and more efficient algorithms.

In this way, our main contribution consists in the obtention of adaptive time discretizations which will allow us to keep the error under a given tolerance thanks to a suitable choice of the step setting and, of course, with a noticeable computational cost reduction.

Numerical experiments will be provided, in particular some involving image processing and filtering where the computational cost is a crucial drawback.

IC/MP88/033: Bifurcation analysis in experiments.

Organiser: Yuliya Kyrychko (University of Bristol, UK)
Co-organiser: Jan Sieber (University of Aberdeen, UK)

The aim of the minisymposium is to present and dicuss methods for the analysis and tracking of bifurcations directly in real-life experiments. The requirement of feasibility in an experiment, which these methods have to satisfy, is fundamentally different from the well-researched numerical efficiency. We aim to bring together experts who have approached this challenging problem from different angles and in various contexts. The approaches we plan to present range from feedback control based on linear system identification or time series analysis to equation-free methodologies, which have been successfully applied to computational black-box simulators.

Bifurcations in impact oscillators. **Celso Grebogi** (University of Aberdeen, UK) IC/MT1692/033

A system is an impact oscillator if it has an oscillating object that impacts frequently with some other object. Impact oscillators occur in many technological situations. For example, mechanical devices are often engineered with loose fitting joints to accommodate thermal expansion, and the dynamical behaviour of such systems often leads to impacts in the joint. In addition, many machines inevitably suffer from effects of vibro-impacts. A common feature shared by models of these systems is the smoothness of the systems between the impacts. In this talk, I will use a simple physical system as a prototype impact oscillator. A mass is attached to a linear spring that is fixed to a wall. There is sinusoidal external force acting on the mass. The friction force is proportional to the velocity of the mass. When the amplitude of oscillation is sufficiently small, there are no impacts between the mass and the wall, and the dynamics of the system is the same as that of a forced damped harmonic oscillator without the wall. As the amplitude of oscillation is increased, the mass begins to have impacts with the wall, first with very low velocity. The bordering state between the impacting and non-impacting is called a grazing impact, i.e., when the mass contacts with the wall with zero velocity. Interesting new bifurcations are observed at grazing, and they are called grazing bifurcations. Grazing bifurcations are important physical examples of a general type of bifurcation called "border-collision bifurcations". The purpose of this talk is to present an analysis of grazing bifurcations in impact oscillators. These bifurcations are "unconventional" in that they do not occur in smooth systems. The bifurcations presented in this talk are, however, expected to be universal for such systems and to apply to many systems in which impacts occur. I will also mention results on the control of impact oscillators when in a chaotic state.

Bifurcations in multi-section semiconductor lasers. **Hans-Jürgen Wünsche** (Humboldt-Universität zu Berlin, Germany), Oleg Ushakov (Humboldt-Universität zu Berlin, Germany), Sylvia Schikora (Humboldt-Universität zu Berlin, Germany), Fritz Henneberger (Humboldt-Universität zu Berlin, Germany) IC/MT2332/033

Multi-section semiconductor lasers represent a new class of optical devices. Their complex dynamics makes them promising candidates for applications in optical communication networks. We summarize experiments with lasers consisting of three individually contacted sections. In the parameter space of the three easily tunable injection currents, they exhibit a rich variety of operational modes. Among them are continuous-wave operation, regular power pulsation, and also chaotic emission. Due to the extremely short time scales between nanoseconds and picoseconds, the underlying bifurcations can be identified only from measured optical and power spectra. To these purposes, the response to external perturbations is used as additional fingerprint of the type of a bifurcation. Examples are the decreasing line width of noise-induced precursurs of Hopf bifurcations and the extremely long chaotic transients upon pulsed excitation close to a boundary crisis. The unstable states born in bifurcations play an important role but usually they are not accessible in experiment because visited at most for short times only. To overcome this difficulty, we have developed an all-optical version of noninvasive time-delayed feedback control. Optical feedback from an external Fabry-Perot resonator is exploited. Path-following of unstable steady and pulsating states beyond Hopf and period doubling bifurcations, respectively, is demonstrated with this method. The experimental results will be supplemented by numerical simulations and a bifurcation analysis of the underlying model equations.

Model-based experimental bifurcation analysis. **Ulrich Parlitz** (Universität Göttingen, Germany), David Engster (Universität Göttingen, Germany), Jörg Dittmar (Universität Göttingen, Germany) IC/MT2257/033

Different modelling methods are employed to predict and track bifurcation points in experimental systems using a few measured time series, only. If no physical model of the underlying process is available black-box models have to be generated from the data which are able to reproduce the observed longterm dynamics including proper parameter dependence. We shall present criteria and strategies for providing such models and practical examples illustrating their performance.

Bifurcations in power electronic converters. **Stephen Hogan** (University of Bristol, UK) IC/MT2769/033

In many control problems, the control strategy is phrased in terms of average quantities. In this paper we prove the general result that, given a linear system $\dot{x} = Ax + u$ where A is hyperbolic, u is piecewise linear and L-periodic, such that $\int_0^L u(t)dt = 0$, then there exists a unique L-periodic solution $x = x_p(t)$ such that $\int_0^L x_p(t)dt = 0$. We then consider a DC/DC buck (step-down) converter controlled by the ZAD (zero-average dynamics) strategy. The ZAD strategy sets the *duty cycle*, d (the length of time the input voltage is applied across an inductance), by ensuring that, on average, a function of the state variables is always zero. The two control parameters are v_{ref}, a reference voltage that the circuit is required to follow, and k_s, a time constant which controls the approach to

the zero average. We show how to calculate d exactly for a periodic system response, without knowledge of the state space solutions. In particular we show that for a T-periodic response d is *independent* of k_s. We calculate curves in (v_{ref}, k_s) space at which a T-periodic response of the system undergoes period doubling and corner collision bifurcations, the latter occurring when the duty cycle saturates and is unable to switch. We also show the presence of a codimension two bifurcation in this system when a corner collision bifurcation and a saddle node bifurcation collide, to produce stable unsaturated $2T$-periodic responses which can be obtained either in the presence or absence of the stable T-periodic response.

Work done in collaboration with E. Fossas and T. M. Seara (Universitat Politècnica de Catalunya, Barcelona, Spain)

IC/MP88/033: Bifurcation analysis in experiments. #2

Design of computational experiments for bifurcation computations. **Yannis Kevrekidis** (Princeton University, USA) IC/MT3032/033

We will discuss equation-free computation as a protocol for design of computational experiments. In particular, we will study cases where the goal of the coarse-grained computation is the location of coarse bifurcation points.

Bifurcations in a spring–pendulum oscillator. **Alicia Gonzalez-Buelga** (University of Bristol, UK), Yuliya Kyrychko (University of Bristol, UK), David Wagg (University of Bristol, UK) IC/MT1161/033

In this paper we study experimentally the dynamics of a non linear system: a spring pendulum coupled to an oscillator. The system was tested using a hybrid technique called Real Time Dynamic Substructuring (RTDS). RTDS is a testing technique that involves splitting the system under study into two subsystems: one will be physically tested (physical substructure) and the other will be simulated in the computer (numerical model). Typically the numerical model is a linear well known behaviour subsystem while the substructure is a nonlinear unknown dynamics subsystem. These substructures interact in real time trough a set of transfer systems.

RTDS is a very powerful experimental methodology that not only allows full scale and real time testing but also real-time bifurcation tracking in complex engineering systems. The fact that part of the system is represented by its numerical model permits manipulation of the systemŠs characteristics in real-time.

In our hybrid experiment the spring pendulum is taken to be the tested physical substructure while oscillator is the simulated numerical model. This presentation focuses on experimental study of single and multi-parameter bifurcations. These studies are not possible from a full physical experiment and show the possibilities of using a hybrid numerical-physical technique.

Global properties of time-delayed feedback control with unstable control loop in electronic circuit experiments. **Klaus Höhne** (TU Darmstadt, Germany) IC/MT2504/033

Time-delayed feedback control is an efficient tool, both in theory and experiment, to stabilize unstable periodic orbits embedded in a chaotic attractor. One of the most important restrictions of this method arises from the so-called odd-number-limitation, i.e. torsionfree unstable periodic orbits cannot be stabilized by conventional time-delayed feedback control. Here we report on experiments in an electronic unstable van der Pol oscillator. We succeeded in controlling a torsionfree unstable periodic orbit by applying the method of an unstable time-delayed feedback controller. Our investigations showed that control often fails due to a small basin of attraction. We found, however, that the global control performance can dramatically be improved by varying the coupling between the system and the control loop. Our experimental findings are consistent with considerations from bifurcation theory and in very good agreement with numerical simulations.

Nonlinear modal interactions and model reduction of a kicked flexible rod. **Joseph Cusumano** (Pennsylvania State University, USA) IC/MT2795/033

We present a detailed experimental study of the dynamics of a flexible steel rod kicked by a spatially triggered electromagnet. This nonlinear oscillator provides an excellent model problem with which to study empirically-assisted methods for generating low-order models from infinite-dimensional dynamical systems.For all values of the kicker magnet voltage V, motions starting with sufficiently small initial conditions asymptotically approach the stable trivial solution of the system. However, above a critical voltage, a bifurcation occurs giving rise to a stable/unstable limit cycle pair. As V increases, spectral bifurcation diagrams show four distinct dynamical regimes: small amplitude limit cycle; quasiperiodic response; chaos; and large amplitude limit cycle. The Proper Orthogonal Decomposition (POD) is used to study the effective dimensionality and modal interactions in the system. It is shown that two specific nonlinear modes dominate in the observed dynamics over the entire range of the kicker voltage, and hence it might reasonably be expected that a two degree of freedom (DOF) model is adequate to describe the observed behavior. Phase space reconstruction of time series data and nonlinear prediction provide an independent confirmation of this effective dimensionality. Motivated by these experimental results, a simple 2 DOF model is developed. It is shown that the model provides a good qualitative match to the experimental system, including both the modal and bifurcation structures. We conclude by discussing some of the difficulties and outstanding research questions in using POD for such model reductions.

IC/MP245/033: Dynamical systems with cosymmetry: numerics, bifurcations, applications.

Organiser: Vyacheslav Tsybulin (Rostov State University, Russian Federation)

A new object in cosymmetrical systems is a family of steady states with variable spectra. This case is the opposite of the symmetry situation when all the states have identical spectrum. It is very interesting to consider the effects produced by the appearance of such a continuous family. Now the non-trivial bifurcations were found in cosymmetrical problems: the delay with limit cycle branching off, new scenario of tori birth etc. The investigation of all these problems has required the development of new numerical methods and the study of approaches in the bifurcation theory of dynamical systems. The

proposed talks will present recent results on the cosymmetry theme. Partially, we plan to consider: Evolution of steady states family in 2d and 3d convection in a porous medium, cosymmetrical effects in some population kinetics problems, numerical approaches to computation of steady states family, special cosymmetrical bifurcations, computer experiment on the selection of steady states from the continuous family.

The co-symmetric bifurcations in the planar filtrational convection problem: numerical results. **Vasily Govorukhin** (Rostov State University, Russian Federation) IC/MT870/033

Theory of cosymmetry was introduced by Yudovich [1] to explain a phenomenon of existence of one-parameter family of stationary flows in the planar filtrational convection problem. It was shown that the branching of cycle of equilibria (CE) is a typical bifurcation in cosymmetric dynamical system [1]. In [2] and in many other works of these authors the theory of cosymmetric bifurcations was developed.

We investigate the planar filtrational convection problem in rectangular container numerically by Galerkin method. We consider Galerkin systems of various dimensions (up to 1000) and we study numerically the bifurcations connected mainly with CE existence.

The bifurcations of CE was found out: birth of a new family from already existing, intersection and join of CE, origin of a CE Šfrom an airŠ etc [3-4]. The bifurcations of families are connected with different CE both with stable and with unstable. The periodic, quasiperiodic and chaotic regimes were founded for different values of parameters [4]. The steady periodic regimes can occur by two ways: as a result of cosymmetric Hopf or Euler bifurcations. For some values of parameter transition from stationary movement at once to chaotic ones is possible. The bifurcation of tori branching from CE was found.

The qualitative repetition of bifurcation and consistency of bifurcation parameter values was established by different dimensions Galerkin's models investigation. We found practically all types of bifurcations studied theoretically in [2].

Co-symmetric families of steady states in 3D convection of the incompressible fluid in a porous medium. **Vyacheslav Tsybulin** (Rostov State University, Russian Federation) IC/MT884/033

Three-dimensional convection of the incompressible fluid in a porous medium is considered. Mimetic finite-difference schemes for the primitive variables equation are developed. The connection of a derived staggered discretization with a finite-difference approach based on the stream function (planar problem) is established. Continuous cosymmetric families of steady states are computed and stability analysis is presented.

Selection of steady states in planar Darcy convection. **Bülent Karaözen** (Middle East Technical University, Turkey), Vyacheslav Tsybulin (Rostov State University, Russian Federation) IC/MT1732/033

Selection of steady states in the planar convection problem for the incompressible fluid in a porous medium is studied. The perturbation of initial data by adding of the harmonic deviation of boundary temperature is analyzed. Computer experiments on the selection of equilibria show that, for initial distribution (disturbance) with large amplitude, the neighborhood of a single preferable steady state is established. The question is why some patterns of fluid are more preferred than others. This problem is may be treated as a some variant of the description of separation processes. Important future problem here is a possibility to control the pattern organization.

Dynamics and family of equilibria in a population kinetics model with cosymmetry. **Katya Kovaleva** (Rostov State University, Russian Federation), Kurt Frischmuth (Universität Rostock, Germany) IC/MT2658/033

This work continues the study have started in [1] with a system of nonlinear parabolic equations with cosymmetry. We assume three populations sharing a common space and suppose a dominant role of the unique spatial coordinate. Looking for best opportunities for their respective trades, each population may move in dependence on the current concentrations of their own kind and the other one. However, the first population (thrives on relocation of the others, while the second and third suffer from motion of the first. We use a finite-difference scheme preserving the cosymmetry property for a given problem. Two cases of boundary conditions are considered. Different scenarios of instability for the state of rest are observed. Numerical results on computation of continuous families of steady states and periodic regimes are presented and stability of the zero equilibrium are studied.

IC/MP79/034: Pattern formation in coupled-cell systems.

Organiser: William Langford (University of Guelph, Canada)

Systems of coupled oscillators (or *cells*) occur in very diverse applications, ranging from animal gaits and neural networks to heat exchanger arrays. Earlier work focussed on systems with a high degree of symmetry, leading naturally to complex spatio-temporal patterns via equivariant Hopf bifurcation theory. Recent work includes more general architectures represented by directed graphs, and reveals new behaviors such as nilpotent bifurcations occurring in codimension one.

Synchrony in coupled systems and the vestibular system. **Martin Golubitsky** (University of Houston, USA) IC/MT3884/034

Synchrony and phase synchrony were first studied in coupled systems using network symmetry. More generally, robust synchrony in a network of identical subsystems (cells) follows from a combinatorial condition (balanced coloring) and robust phase synchrony corresponds to symmetry in quotient networks. We review this earlier work and discuss phase shift synchrony in the context of that part of the vestibular system which connects inner ear canal nerves with neck muscle motoneurons. This later work is joint with Ian Stewart and LieJune Shiau.

Coupled cell networks: minimality and quotients. **Manuela Aguiar** (Universidade do Porto, Portugal), Ana Dias (Universidade do Porto, Portugal), Martin Golubitsky (University of Houston, USA), Maria Leite (University of Purdue, USA), Ian Stewart (University of Warwick, UK) IC/MT3902/034

Non-isomorphic coupled cell networks can correspond to coupled-cell systems with equivalent dynamics and are called ODE-equivalent. Coupled cell systems restricted to flow-invariant subspaces defined by equality of certain cell coordinates correspond to quotient networks. In this talk we discuss some recent results related with ODE-equivalence of coupled cell networks, minimality of ODE-classes and quotients networks.

Stability computations for nilpotent Hopf bifurcations. **Maciej Krupa** (New Mexico State University, USA), Martin Golubitsky (University of Houston, USA) IC/MT3948/034

Nilpotent Hopf bifurcations can occur in codimension one in coupled cell systems. Elmhirst and Golubitsky studied such bifurcations and obtained rather unusual branching patterns. In this work we use normal form theory to obtain stability results for some of the branches found by Elmhirst and Golubitsky. On the way to obtaining our results we determine how some of the synchrony subspaces of the network influence the structure of the normal form.

Spatio-temporal patterns in heat-exchanger arrays. **William Langford** (University of Guelph, Canada) IC/MT3930/034

Flow-induced vibrations of the tubes in a large heat exchanger array can cause metal fatigue and failure, leading to costly repairs. A simple mathematical model is presented for the case of a rectangular array, so that the problem becomes a study of the spatio-temporal patterns in a two dimensional coupled cell system with $\mathbb{Z}_M \times \mathbb{Z}_N$ symmetry. The results presented here include all the generic equivariant Hopf bifurcations in this setting, with their onset, stability and spatio-temporal patterns, for cases with the spatial periodicities that are likely to occur, both with and without an internal $\mathbb{Z}_2$ symmetry. The predictions of this analysis are in good qualitative agreement with experiments on flow-induced vibrations in arrays of circular cylinders performed at Atomic Energy Canada Limited. This is joint work with R. Akila, Garyounis University, Benghazi, Libya.

IC/MP326/034: Symmetry aspects in biological dynamical systems.

Organiser: LieJune Shiau (University of Houston, USA)
Co-organiser: Marc Timme (Max-Planck-Institut Göttingen, Germany)

This minisymposium features novel results on models of various biological dynamics, with a focus on underlying symmetries and on breaking these symmetries. Topics range from mechanisms of muscle movements to pattern formation and non-standard dynamics in biological neural networks.

In particular, one study is about the principles of neck muscle movements in most vertebrates (including humans), based on the semicircular canal input from the ears in the vestibular (balancing) system. Two studies investigate heteroclinic networks and unstable attractors, arising naturally in networks of neural oscillators. These features lead to the phenomenon of switching between neural *encoding* states, with potential implications, among others, for odor recognition and processing in insects. Another one shows that the number density of singular points, called pinwheels, in cortical pattern forming systems follows a universal statistics, with its mean normalized density close to the mathematical constant π. A theoretical model of pattern formation in the cortex explains this result. Also, a new dynamical phenomenon is found and analyzed in the study of globally coupled neural networks. Here the dynamics shows the irregular and chaotic appearing in transients, although it is governed by negative Lyapunov exponents. A relation to *stable chaos* is also discussed.

All speakers will present the basics and symmetries of the biological systems studied, and discuss their results.

Heteroclinic networks and clustering in simple models of neural activity. **Gábor Orosz** (University of Exeter, UK), Peter Ashwin (University of Exeter, UK) IC/MT1991/034

The dynamics of neural systems has to balance seemingly contradictory requirements of robustness to noise and sensitivity to inputs. Networks of coupled systems can however deliver this in cases where they have attractors that are heteroclinic networks giving so-called 'winnerless competition' between unstable states. We consider some specific examples motivated by work on the insect antennal lobe that convert spatially dependent inputs into spatio-temporal codes, where one can verify robustness with high sensitivity to inputs.

Stability properties of the asynchronous regime in a network of identical neurons. **Antonio Politi** (Consiglio Nazionale delle Ricerche, Italy) IC/MT991/034

The stability of globally coupled neurons is usually carried out by following a mean field approach. With reference to a system of leaky-integrate-and-fire neurons, we develop a microscopic approach that allows for an exact stability analysis. As a result we find that the mean field approach does not always provide the correct answer. This is issue is connected to the noncommutativity of two limits: infinitely many neurons and delta-like pulses. We also discuss the occurrence of some bifurcations that break the time-invariance of the asynchronous regime and the effect of a small dilution (cutting some links) which may give rise to a linearly stable but irregular regime.

Symmetry and bifurcation in vestibular system. **LieJune Shiau** (University of Houston, USA), Martin Golubitsky (University of Houston, USA) IC/MT1485/034

The vestibular system in most vertebrates, particularly in humans, controls balance by six semicircular canals to detect angular accelerations of the head motion. Signals from the canals are transmitted to eight groups of neck motoneurons thus the eight corresponding muscle groups. Through symmetry architecture and coupled cell network, we show that there are six possible spatiotemporal time-periodic states that can arise by Hopf bifurcation from an equilibrium representing an immobile head. We interpret these patterns as motions of the head and note that all six types of pattern appear to correspond to natural head motions.

Linearly-unstable attractors: charge loss induces heteroclinic switching in spiking neural networks. **Marc Timme** (Max-Planck-Institut Göttingen, Germany) IC/MT1591/034

The brain processes information in networks of nerve cells (neurons) which interact by sending and receiving electrical pulses, called spikes. The response of a biological neuron to incoming signals strongly depends on whether or not it has just emitted a spike. Here we propose a simple model of coupled neurons with partial response to residual input charges after spike emission. We study their collective network dynamics in the regime where the individual neurons dynamics is oscillatory and the interactions are delayed. For concave rise functions the system exhibits heteroclinic switching between cluster states (saddle periodic orbits) for an open set of a charge-loss parameter. We show that the saddle periodic orbits become unstable attractors (linearly unstable periodic orbits that are attractors in the sense of Milnor) in the limit of complete charge-loss, where the system becomes non-invertible.

IC/MP326/034: Symmetry aspects in biological dynamical systems. #2

Organiser: LieJune Shiau (University of Houston, USA)
Co-organiser: Marc Timme (Max-Planck-Institut Göttingen, Germany)

(For abstract, see session #1 above.)

Symmetry in sympathy: speciation as pattern formation in phenotype space. **Toby Elmhirst** (University of British Columbia, Canada) IC/MT3419/034

It has long been debated whether dimorphism can arise in a monomorphic population in a homogeneous environment, or whether a species can only diversify if different populations are geographically isolated from each other. I will present a class of systems, known as "pod systems", that brings out the symmetry of this question, and shows that dimorphism can appear in a population through a symmetry-breaking bifurcation. Thus we can see the appearance of biological diversity as pattern formation in phenotype space.

The general approach is to view a population as a density distribution over phenotype space. A monomorphic population is thus seen as a unimodal distribution, and a dimorphic one is bimodal. The systems I will discuss allow us to view the dynamics of a distribution over a spatial domain in terms of an $\mathbf{S}_N$-equivariant system of ODEs. The action of $\mathbf{S}_N$ means that a fully symmetric solution is a unimodal distribution — a marked difference from the usual symmetry-breaking analysis of systems on a domain in which fully symmetric solutions are spatially homogeneous. Thus we are able to analyse symmetry-breaking bifurcations from unimodal distributions, and we find that at primary symmetry-breaking bifurcations there exists, generically, a unique branch of bimodal distributions.

A mathematical constant in the design of the visual cortex. **Fred Wolf** (Max-Planck-Institut Göttingen, Germany) IC/MT3021/034

In the cortex of the mammalian brain, visual information is processed by a complex 2-dimensional pattern of functional modules called the orientation preference map. Because in young animals this structure is thought to arise by a dynamics of neuronal development a central aim of current research is the identification of dynamical models that can reproduce its spatial organization. Recently, the introduction of biologically plausible symmetry principles has enabled the identification of promising candidate models of visual cortical circuit development.

To provide a firm basis for comparing experimental observations and the predictions of such models, we quantitatively characterized the spatial statistics of singular points, called pinwheel centers, in orientation preference maps in a wide variety of animal species including monkeys, carnivores, and shrews. These species have evolved separately for more than 50 million years, occupy different ecological niches, and exhibit distinct patterns of visual behavior. Surprisingly, we found that numerous statistics of singular points including their spatial density, their count variance, and the next neighbor distance distributions of singular points are quantitatively indistinguishable, i.e. universal in the species studied. Most suggestive of a mathematical structure underlying this universality, the mean non-dimensional spatial density of singular points turned out to be 3.14 ± 0.03 being statistically indistinguishable from a well known mathematical constant.

Theoretical analyzes show that the observed universal statistics are quantitatively reproduced by models of cortical self-organization exhibiting a recently introduced permutation symmetry if their behavior is dominated by long-range interactions. We conclude that the experimentally observed universal statistics are emergent signatures of a dominant role of long-range interactions in the self-organization of cortical neuronal circuits.

Critical branching processes in neural networks. **Anna Levina** (Universität Göttingen, Germany) IC/MT3918/034

Self-organized critical dynamics occurs in a variety of systems. Commonly the activity of such systems during avalanches is modeled by branching processes. Under certain circumstances, this approach is justified by the specific topology of the system. In the sandpile model, for instance, an active site can activate only lower lying neighbours and cyclic activation is impossible.

Recent experimental research gave evidence of critical avalanches generated by a system far more complicated than a sendpile: neuronal activity in slices of rat cortex and neuronal cultures exhibit critical avalanche dynamics in the propagation of spontaneous activity. To model these more complicated dynamics, for simplicity, also branching processes were used, although it is unclear whether these are an appropriate approximation even for highly recurrent networks.

Here we establish a direct correspondence between avalanches generated by a critical branching processes and by a fully connected network of integrate-and-fire neurons. Such networks has been shown to exhibit power-law avalanches distribution observed experimentally. We present strong evidence justifying use of the branching processes for simulation and analysis of recurrent neural networks.

The discovered correspondence leeds to the suggestion of the simple learning rule, which allows self-organization of the network towards critical state.

IC/MP279/034: Geometry, dynamics, and control.

Organiser: Dmitry Zenkov (North Carolina State University, USA)
Co-organiser: Anthony Bloch (University of Michigan, Ann Arbor, USA)

This minisymposium focuses on a wide range of applications of geometric methods to dynamics, mechanics, and control. The following areas will be addressed, among others: dynamics and bifurcations in networks of identical coupled systems, exponential maps, reduction theory, decoding algorithms from the dynamical system point of view, and a dynamical system approach to control and stabilization. The unifying theme is the use of geometrical methods in dynamical systems.

A connection theoretic approach to reduction of second-order dynamical systems with symmetry. **Tom Mestdag** (The University of Michigan, USA) IC/MT1434/034

There are several different geometric contexts in which we find manifestations of the following behaviour: roughly speaking, there is a system of second-order ordinary differential equations which admits a Lie group of symmetries; this system is reduced to a coupled pair of sets of equations, one of second-order (albeit in a generalized sense) and one of first-order. Some examples are: the geodesics of a manifold with a Kaluza-Klein metric (Wong's equations); simple mechanical systems with symmetry, including control systems; Lagrangian reduction (Lagrange-Poincare equations) and non-abelian Routh reduction (Lagrange-Routh equations). In different cases different auxiliary geometrical structures are required to carry out the reduction. In the present talk we shall explain the nature of this reduction process for a dynamical system governed by second-order differential equations, which is invariant under a Lie group action, using thus the simplest type of auxiliary machinery imaginable. We show that, in fact, the systems decompose in three parts. It is our aim to explain how this decomposition arises, with the help of connection theory; and to discuss the processes of reduction and reconstruction from this standpoint.

Discrete mechanics and control on Lie groupoids. **Eduardo Martínez** (Universidad de Zaragoza, Spain) IC/MT1990/034

Discrete Lagrangian Mechanics on Lie groupoids was introduced in[1] and further developed in[2]. This formalism allows to describe the discrete analogs of continuous systems on Lie algebroids, as can be obtained, for instance, by an adequate discretization.

Such results can be naturally extended for discrete-time optimal control problems defined on Lie groupoids. By an adequate study of the admissible variations we will find the optimality conditions, that will be expresed in terms of composability in a groupoid.

We will show some examples and we will further study symmetry and reduction theory. In particular, the discrete Euler-Lagrange equations for a discrete mechanical system on a Lie groupoid are obtained as a particular case.

[1] A. Weinstein; Lagrangian Mechanics and groupoids. Fields Inst. Comm. **7** (1996) pp.207–231.

[2] Marrero, J.C., Martín de Diego, D. and Martínez, E.; Discrete Lagrangian and Hamiltonian mechanics on Lie groupoids, Nonlinearity **19** (2006) pp.1313–1348.

Systems theoretic questions in coding theory. **Joachim Rosenthal** (Universität Zürich, Switzerland) IC/MT1790/034

A central theme of current research in coding theory are low density parity check (LDPC) codes and more general codes defined via graphs. There exist various decoding algorithms which work in a decentralized manner and which can be viewed as a discrete dynamical system. In this talk we explain these algorithms from a systems theoretic point of view.

Stabilization of discrete mechanical systems. **Dmitry Zenkov** (North Carolina State University, USA), Anthony Bloch (University of Michigan, Ann Arbor, USA), Melvin Leok (Purdue University, USA), Jerrold Marsden (California Institute of Technology, USA) IC/MT1124/034

In this talk we discuss the controlled Lagrangian approach to feedback stabilization of discrete mechanical systems with symmetry. We describe new phenomena that arise in the controlled Lagrangian approach for mechanical systems in the discrete context. We also discuss digital and model predictive controllers.

IC/MP279/034: Geometry, dynamics, and control. #2

Organiser: Dmitry Zenkov (North Carolina State University, USA)
Co-organiser: Anthony Bloch (University of Michigan, Ann Arbor, USA)

(For abstract, see session #1 above.)

Bifurcations in small networks of identical coupled systems. **Martin Golubitsky** (University of Houston, USA) IC/MT1784/034

There are many special features that occur generically in bifurcations from synchrony in small networks of differential equations. The situation is reminiscent of bifurcations in systems with symmetry, but here the special mathematical structure is due to the way that the identical systems are coupled. We discuss several surprising examples of generic bifurcations that occur in small networks.

Convexity, reduction, and dynamics. **Tudor Ratiu** (École Polytechnique Fédérale de Lausanne, Switzerland) IC/MT2754/034

Convexity properties of momentum maps are intimately related to bifurcation phenomena in Hamiltonian systems with symmetry. This talk surveys recent progress in the convexity properties induced by symplectic actions and their relationship to reduction theory. The most general convexity theorem is associated to an arbitrary symplectic action of a Lie group, is metric in nature, and does not require the existence of a momentum map. The results presented in this survey are based on several papers written jointly with P. Birtea and J.-P. Ortega.

Geometry of integrable systems and optimal control. **Anthony Bloch** (University of Michigan, Ann Arbor, USA) IC/MT2361/034

In this talk I will discuss the dynamics and geometry of certain dynamical systems arising from optimal-control problems and the maximum principle . In particular I will discuss various integrable Hamiltonian systems that arise in this context. This includes the study of various geodesic flows on manifolds including Stiefel manifolds, the study of generalized rigid body equations and certain subRiemannian optimal control problems. I will discuss such systems in both the smooth and discrete settings.

Riemannian exponential maps of the diffeomorphism group on a flat 2D-torus. **Thomas Kappeler** (Universität Zürich, Switzerland), Enrique Loubet (ETH Zürich, Switzerland), Peter Topalov (Northeastern University, USA) IC/MT1877/034

We study exponential maps induced by Sobolev type right-invariant weak Riemannian metrics of order $k \geq 0$ on the Lie group of smooth, orientation preserving diffeomorphisms of the two dimensional torus and prove that for $k \geq 1$, but not for $k = 0$, each of them defines a smooth Frechet chart of the identity.

IC/MP40/036: Euler and space exploration.

Organiser: Martin Lo (Jet Propulsion Laboratory, USA)

The exploration of space is typically thought of as an engineering endeavor, but actually, mathematics, both pure and appliced, play a very important role. Euler is a case in point: his work on the Three Body Problem is today one of the cornerstones of modern astrodynamics. This minisymposium will describe some of the latest research and development on space missions, like the James Webb Telescope, where Euler's work plays a key role.

Central to this is dynamical systems theory, first studies in Poincare's seminal work on the Three Body Problem where he discovered dynamical chaos. Today, chaotic orbits enable numerous ultra-low-fuel missions around the Solar System. Recent work has shown that the transport of materials in the Solar System is governed by the chaotic dynamics of the collinear solutions that Euler discovered some three centuries ago, what we now call the L1, L2, and L3 *Lagrange Points*. Several of our speakers first introduced this approach to space mission design and will describe their latest work on the subject.

Although the dynamics of Euler's solutions play a fundamental role in the design of these trajectories, the use of advanced propulsion technology created many new and challenging problems. In particular the optimization of trajectories using low thrust ion engines is highly complex and interesting. Several of our speakers will address this problem.

Another interesting problem is the use of of satellites flying in formation around L2. They are typically used for astronomy missions that require long baseline interferrometers. Some of our speakers will describe the precision control of these formations in this highly nonlinear regime.

Euler would be delighted and amazed to find how his collinear orbits have made such a huge impact on space exploration and our understanding of the chaotic dynamics of the Solar System.

Space-craft insertion in unstable environments: application to formation flight near the libration points. **Benjamin Villac** (UC Irvine, USA) IC/MT4493/036

The stable manifold associated with the periodic and quasi-periodic orbits has proved a key concept for the low cost transfer of spacecraft to libration point regions. Recent interest in formation flight near the libration points opens the question of precise spacecraft insertion along a nominal orbit. While current approaches emphasize the station-keeping and (re)configuration of such formation – and thus consider the insertion problem from a control viewpoint –, we propose a purely dynamical mechanism for spacecraft insertion and servicing in formation flight. By analyzing the rate of convergence of the orbits on the stable manifolds of the target libration point trajectory, opportunities for low cost transfer to a specific location on the target orbit are determined.

Invariant manifolds and the interplanetary super-highway. **Martin Lo** (Jet Propulsion Laboratory, USA) IC/MT4494/036

The classical view of the Solar System since the time of Copernicus and Kepler is an orderly universe centered on the Sun with the planets revolving in isolated near-circular orbits. But the work of Wisdom and Laskar have shown the Solar System is not so regular and orderly, but instead, it is chaotic. At the heart of this chaos are the invariant manifolds associated with the 3-body solutions discovered by Euler, what is now called the collinear Lagrange Points. If we view the Solar System as a series of coupled 3-body problems, these manifolds intersect in configuration space and sometimes in phase space to provide an ultra low energy transport from the Kuiper Belt to the Sun. This is the *Interplnaetary Superhighway* which plays a significant role in the transport and morphology of the Solar System from the zodiacal dust, the rings, the asteroid belt, to the comets.

In the 1960s Farquhar discovered the 3-dimensional periodic *halo orbits* around the collinear Euler points. In 1978, the first space mission flew in this unique orbit under Farquhar's leadership. During the 1980s the Barcelona school under Carles Simo, Gerard Gomez, and their colleagues, introduced the use of dynamical systems theory to the design of space trajectories. This work inspired Howell and Lo to apply invariant manifolds to NASA missions in the mid 1990s. This led to the design of the Genesis trajectory by Lo and Howell's group using the heteroclinic behavior between L1 and L2. It also inspired the investigation that led to Lo's discovery of the Interplanetary Superhighway with the help of his student Ross. In order to understand the heteroclinic dynamics of the Genesis orbit, Lo turned to Marsden and his student Koon for help. Together, they extended the work of Llibre, Martinez and Simo on homoclinic orbits to heteroclinic orbits to explain the Genesis orbit.

We will discuss the implications of this network in our Solar System for science and space exploration.

Leaving and reaching the moon from a libration-point orbit. **Gómez-Muntané Gerard** (Universitat de Barcelona, Spain), Masdemont Josep (Universitat Politècnica de Catalunya, Spain), Elisa Maria Alessi (Universitat de Barcelona, Spain) IC/MT4499/036

Using the hyperbolic invariant manifolds of the central manifolds of L1 and L2 in the Earth–Moon system, we explore the collision orbits with the surface of the Moon. Applications to mission analysis and astronomy will be presented.

Low-thrust mission analysis methods and results for the ESMO-SEP mission. **Daniel Novak** (University of Glasgow, UK), Jeannette Heiligers (TU Delft, The Netherlands), Camilla Colombo (University of Glasgow, UK), Massimiliano Vasile (University of Glasgow, UK) IC/MT4997/036

The European Student Moon Orbiter (ESMO) mission aims at injecting a micro-satellite class spacecraft into an orbit around the Moon by 2011. In addition to the scientific goal, the whole project aims at a design completely carried out by several students over Europe, working together in a virtual concurrent engineering environment. The stringent requirements on the cost and the reliability of the mission have a strong impact on the mission analysis: the trajectory must be reliable (to minimise the risks), the transfer time should be as short as possible, and ground stations must be chosen accurately (to reduce the ground segment cost). This paper focuses on one of the two investigated options for the transfer to the Moon: a low-

thrust transfer through the Lagrangian point L_1. The transfer trajectory is composed of a spiral winding up from a GTO to almost L_1, transfer through the neighbouring region of L_1 and final spiral winding down to an orbit that can guarantee six months of operations. The paper will present the complete mission analysis for the low-thrust option in addition to a description of the methodology used to design the low-thrust, low-energy transfer through L_1.

IC/MP40/036: Euler and space exploration. #2

Organiser: Martin Lo (Jet Propulsion Laboratory, USA)

(For abstract, see session #1 above.)

BepiColombo gravitational capture and the elliptic restricted three-body problem. **Stefano Campagnola** (University of Southern California, USA), Martin Lo (Jet Propulsion Laboratory, USA) IC/MT4544/036

BepiColombo is the cornerstone ESA-approved mission to Mercury. It will reach its destination in 2019, after a nearly 5-year long transfer using multiple gravity assists and low-thrust propulsion. To avoid a single point failure of a classical chemical orbit insertion burn, an arrival scenario was implemented where the gravity of the Sun is exploited to weakly capture the spacecraft in a Mercury orbit. This technique can be better understood in the frame of the elliptic three-body problem model. In particular, Gravitational Capture conditions are investigated, together with the allowed region of motions for the spacecraft.

Challenges of NASA prospective libration missions. **David Folta** (NASA Goddard Space Flight Center, USA) IC/MT4548/036

As the future unfolds for NASA in its pursuit of the Vision for Space Exploration, libration orbits play a prominent role. Both Sun-Earth and Earth-Moon regions will be exploited requiring mathematical advancements and comprehensive demonstrations. With several successful single missions, new challenges of formation flying, intra-transfer orbits, and unique station-keeping strategies take center stage. Mathematical applications to improve and otherwise optimize mission parameters are necessary to permit communication and exploration architectures of the exploration vision. Recent advancements, which apply EulerŠs grid technique, is one example. The paper focuses on potential missions and how recent advancements based on EulerŠs imaginings make these missions possible.

Design strategies for libration-point missions: theory to application. **Kathleen Howell** (Purdue University, USA) IC/MT4549/036

Spacecraft missions to the libration points in sun–planet and planet–moon systems are of increasing interest. A number of such missions have already been launched. As the theoretical understanding of the dynamical structure in these regions of space expands, however, trajectory design to support actual mission requirements is more complex. Baseline trajectories for some recent mission scenarios are presented. Example approaches for transition of the designs to higher fidelity models is discussed.

IC/MP344/036: Mathematical models and computational methods for nano- and bio-technologies.

Organiser: Roderick Melnik (Wilfred Laurier University, Canada)
Co-organiser: Jack Tuszynski (Cross Cancer Institute, Edmonton, Canada)

Most cutting edge developments that are taking place in nano and bio-technologies rely heavily on advances in mathematical modeling and computational methodologies. Examples include, but not limited to, new technologies based on low-dimensional semiconductor nanostructures such as quantum dots, nanotubes, sensors and actuators, drug discovery methodologies, protein- and macrotubule-based devices, techniques, and processes in designing biomolecular motors.

Development and integration of mathematical modeling techniques into these nano- and bio- technologies is an essential pre-requisite for further progress in this increasingly inter-disciplinary field. At the same time, problems that are arising from the development of new nano- and bio- technologies present challenges to applied mathematicians, stimulating advances in differential, difference, and integral equations, numerical analysis and computational mathematics among other fields.

This minisymposium has two aims. The first is to demonstrate some of the key mathematical and computational challenges associated with the state-of-the-art developments in new nano- and bio-technologies, focusing on several representative examples. The second is to expose the more technologically oriented part of the community to most advanced mathematical and computational techniques that are currently being developed in the field, and thus to encourage inter-disciplinary collaborations.

On the interconvesion integral equation for relaxation and creep. **Robert Anderssen** (CSIRO, Australia), Frank de Hoog (CSIRO, Australia) IC/MT1401/036

Because of the particularization of genetic activity that they perform, rheological phenotypes are playing an increasingly important role in biotechnology research including quantitative trait loci (QTL) analysis. For the determination of such phenotypes, the viscoelastic nature of biomaterials must be taken into account. The rheological characteristics of viscoelasticity are normally modelled, as a function of the time t, in terms of the relaxation $G(t)$ and the creep (retardation) $J(t)$ functions. Different instruments are available for performing the associated relaxation and creep experiments, which generate the stress-strain relaxation and creep data from which estimates $G_{est}(t)$ and $J_{est}(t)$ of $G(t)$ and $J(t)$ are recovered. In many situations, only a single instrument is available which can only perform on of these experiments. Consequently, there is considerable interest in computational techniques which allow $J_{est}(t)$ or $G_{est}(t)$ to be determined from the other using the interconversion relationships

$$\int_{)}^{t} G(t-s)J(s)ds = \int_{0}^{t} J(t-s)G(s)ds = t.$$

Though this matter has been examined numerically in the rheological literature, a formal mathematical comparison of the two possibilities has never been undertaken. This talk will report on the results from recent mathematical investigations.

Coupled nonlinear effects in nano-structures and their applications. **Roderick Melnik** (Wilfred Laurier University, Canada) IC/MT3238/036

We demonstrate that the conventional application of linear mathematical models to the analysis of optoelectronic properties of nanostructures in bandstructure engineering may be inadequate for new emerging applications. Examples are given for several types of low-dimensional semiconductor nanostructures, where we account consistently for nonlinear strain and piezoelectric effects in calculating their properties, and for carbon nanotube based devices such as field emitting diodes. A major focus in this talk is given to the analysis of quantum dots, where it is essential to account for coupled effects.

This is a joint work with R. Mahapatra, N. Sinha, J.T.W. Yeow, D.A. Jaffray, M. Willatzen, B. Lassen, and L. Lew Yan Voon

Computational models for the numerical simulation of voltage-operated channels in nano-bio-electronics. **Riccardo Sacco** (Politecnico di Milano, Italy), Bice Chini (Consiglio Nazionale delle Ricerche, Italy), Joseph Jerome (Northwestern University, USA), Massimo Longaretti (Politecnico di Milano, Italy), Giovambattista Marino (Politecnico di Milano, Italy) IC/MT1388/036

In this lecture, a novel mathematical and computational model is proposed for the numerical simulation of Voltage Operated ionic Channels (VOC) in Nano–Bio–Electronics applications. This is a first step towards a multi–physics description of hybrid bio–electronical devices such as bio–chips. The model consists of a coupled system of nonlinear partial differential equations, comprising a Poisson-Nernst-Planck system to account for electro-chemical phenomena, and a Navier–Stokes system to account for fluid–mechanical phenomena. Suitable functional iteration techniques for problem decoupling and finite element methods for discretization are proposed and discussed. Numerical results on realistic VOCs illustrate the validity of the model and its accuracy by comparison with relevant computed channel equivalent electrical parameters with measured data.

Can we predict DNA biological activity by modelling its fluctuations?. **Michel Peyrard** (École Normale Supérieure de Lyon, France), Santiago Cuesta Lopez (École Normale Supérieure de Lyon, France), Dimitar Angelov (École Normale Supérieure de Lyon, France), Titus Van Erp (Katholieke Universiteit Leuven, Belgium), Johannes-Geert Hagmann (École Normale Supérieure de Lyon, France) IC/MT1563/036

DNA dynamics is essential for its biological function. The genetic code could not be read without a local unwinding of the double helix, and large openings, the so-called "DNA bubbles", are supposed to allow the formation of some specific DNA structures such as the T-loop that stabilises the end of the chromosomes, or to affect the binding of proteins.

Mesoscopic models give a fairly accurate description of the thermal denaturation of DNA, i.e. the separation of the two strands by heating, and they predict the existence of localised fluctuations which are reminiscent of the "breathing" of the double helix observed by biologists. Thus it is tempting to try to use these models to predict the biological activity of DNA.

From experimental studies it has been speculated that the formation of bubbles of several base-pairs length, due to thermal fluctuations, is an indication of biologically active sites. A comparison between molecular dynamics simulations of the PBD model of DNA and experiments suggested that calculations could be used to detect such sites [1], but this observation is however not very reliable because the occurrence of large bubbles is rare, even in long simulations, so that the statistical significance of the results can be questioned.

We introduce a method that is orders-of-magnitude faster than molecular dynamics to analyse these bubbles [2,3] and discuss experiments which measure the local fluctuations of DNA as a function of its sequence. We show how they can be used to improve present models to make them more accurate to describe DNA properties [4], and ultimately approach the goal of determining the fluctuations of heterogeneous DNA sequences from physical studies of a highly simplified model and understanding their relation to biological activity.

Multiscale simulations of complex materials for engineering and biological applications. **Simone Melchionna** (Università degli Studi di Roma "La Sapienza", Italy), Efthimios Kaxiras (Harvard University, USA) IC/MT2355/036

A variety of physical phenomena involve multiple length and time scales. In such systems, the changes in bonding and atomic configurations at the microscopic, atomic level have profound effects on the macroscopic properties, be they of mechanical or electrical nature. Linking the processes at the two extremes of the length scale spectrum is the only means of achieving a deeper understanding of these phenomena and, ultimately, of being able to predict and control them.

While methodologies for a single scale are well developed in many fields of physics, chemistry or engineering, methodologies that couple scales present important challenges at the conceptual and computational level. In this talk we review the development of methodologies for simulations across disparate length scales and present illustrative examples, including hydrogen embrittlement of metals [1], DNA conductivity and translocation through nanopores [2], and the use of surface chemical modification to control the wettability of surfaces for biological applications [3].

The role of nonlinearities in the biophysical properties of cytoskeletal components. **Jack Tuszynski** (Cross Cancer Institute, Edmonton, Canada) IC/MT2982/036

This paper discusses the role of nonlinearities in the physical description of several key biomolecules that participate in a number of crucial subcellular processes, namely actin, microtubules and ions crowding around these filaments. We show that the assembly kinetics of actin is a nonlinear process that requires not only a mechanism of saturation but also annealing and fragmentation that are governed by coupled nonlinear equations involving monomer concentration and filament number as the key dynamical variables. The observed dendritic growth of actin networks in cell motility phenomena is subsequently described by the coupling of actin filaments to the protein called Arp 2/3. We then investigate the role of nonlinear dynamics in the formation of microtubules. First of all, spaceflight laboratory experiments have shown that the in vitro and in vivo self-organization of microtubules is sensitive to gravitational conditions. We propose a model of self-organization of microtubules in a gravitational field. The model is based on the dominant chemical kinetics. The pattern formation of microtubule concentration is obtained: 1) in terms of a moving kink in the limit when the disassembly rate is negligible, and 2) for the case of no free tubulin and only assembled microtubules present. The results of our simulations are in good quantitative agreement with experimental data. Next, we present a recently proposed model of molecular and bulk elastic properties of microtubules that include macroscopic estimates of the anisotropic elastic moduli of microtubules, accounting for the molecular forces between tubulin dimers: for a longitudinal compression, for a lateral force and for a shearing force. At the level of large bending motions of microtubule filaments, a continuous medium model is proposed describing a microtubule as an elastic rod. Keeping the dominant nonlinear terms in the bending dynamics equation, we found that when the microtubule is subjected to bending forces, the deviation angle satisfies a Sine-Gordon equation. Particular analytical solutions of this equation are found which describe kink and anti-kink bending modes that may propagate at a range of velocities along the length of the microtubule. Kinetic energies and characteristic damping times of these modes are calculated for different propagation velocities and compared with thermal and ATP hydrolysis energies. Finally, we discuss how coupled differential equations describing the interactions between ions in solution and the filament they surround can lead to solitonic signal transmission.

The walking molecules kinesin *and* myosin. **Hannes Bolterauer** (Universität Gießen, Germany) IC/MT3739/036

We discuss the principal ideas of existing models for kinesin, NCD and Myosin, which are existing motorproteins inside the cell. We find that in order to explain uni-directionality, but also the different directions of walking of ordinary Kinesin and NCD, we cannot use one-dimensional models or quasi-one-dimensional models. Instead we have to describe the two heads as extended objects in an, at least, two-dimensional space. Our model of directed binding uses the natural elasticity of the molecules and explains the general excepted hand over hand movement in different directions. We establish the Langevin and Fokker–Planck description and try to solve it. Our results are in agreement with existing experiments. The described mechanism could be a basis to construct artificial molecular motors.

Modeling the asynchronous circuits: absolutely inertial delays. **Serban Vlad** (Oradea City Hall, Romania) IC/CT702/015

The detail level modeling of the asynchronous circuits from the digital electrical engineering (logical gates and wires) is made with the mathematical models of the delay circuits, called delays and with Boolean functions. A delay is a multi-valued function f that associates to each input $u : \mathbf{R} \to \{0,1\}$ a set of states $x \in f(u), x : \mathbf{R} \to \{0,1\}$ so that a stability property be fulfilled. We suppose the existence of $\delta_r \geq 0, \delta_f \geq 0$ so that for all u and all $x \in f(u)$ the switch of x from 0 to 1 (from 1 to 0) implies that x remains constant equal with 1 (constant equal with 0) more than δ_r time units (than δ_f time units); then f is called absolutely inertial.

The work analyses the absolutely inertial delays from the point of view of the order, the duality, the serial connection, the intersection, the union and the time invariance. Alternative definitions of absolute inertia and several examples are given. We eventually define a special case of absolutely inertial delays, the Zeno delays.

Empirical study of the rate of convergence of some fixed point iterative methods. **Vasile Berinde** (North University of Baia mare, Romania), Mădălina Păcurar (Universitatea Babeş-Bolyai, Romania) IC/CT1859/003

From a practical point of view (that is, from a *numerical* point of view), a fixed point theorem is valuable if, apart of ensuring the existence (and possible, uniqueness) of the fixed point, it satisfies at least the next two requirements (see, e.g., [1]):

(a) it is able to provide an error estimate for the iterative process used to approximate the fixed point;
(b) it provides explicit information on the stability of this iterative method or, equivalently, on the data dependence of the fixed point.

Only a few fixed point theorems in literature are known to fulfill the two requirements and, generally, this is done mainly for the Picard iteration in conjunction with various strong contractive type conditions. Under weaker contractive conditions, the general problem of studying the rate of convergence of fixed point iterative methods arises usually into the next two different contexts, see [2,3,4,5]:

1) For a certain fixed point iterative method (Picard, Krasnoselskij, Mann, Ishikawa etc.) we do not know an *analytical* error estimate. In this case we can try an *empirical* study of the rate of convergence.
2) For large classes of operators (like quasi-contractions) two or more fixed point iteration procedures are known to be able to approximate the fixed points. In such situations, it is of theoretical and practical importance to compare these methods with regard to their convergence rate, in order to establish, if possible, which one converges faster, w.r.t. a certain concept of rate of convergence.

The main aim of this paper is to illustrate how, in the absence of theoretical results, we can perform an empirical study of the rate of convergence of fixed point iterative methods, using the FIXPOINT software package, specially designed for this purpose. The empirical approach of the rate of convergence of fixed point iteration procedures was firstly considered by B.E. Rhoades [6,7,8]. This problem is still of real scientific interest and perspective because it also offers the possibility of inferring theoretical rate of convergence from empirical observations, like in [2,3], which could be very useful when applying these methods to solve concrete problems of industrial and applied mathematics. A survey of the most significant results in this area, together with some open problems, are finally pre-

sented.

An evaluation of test statistics for detecting temporary change in $BL(1,1,1,1)$ models. **Azami Zaharim** (Univeristi Kebangsaan, Malaysia), Amiruddin Ismail (Subang Jaya, Malaysia), Shahrum Abdullah (Universiti Kebangsaan Malaysia), Ibrahim bin Mohamed (University of Malaya, Malaysia), Ibrahim Ahmad (Univeristi Kebangsaan, Malaysia) IC/CT4462/032

A study is carried out to investigate the sampling properties of the outlier test statistics of a procedure developed for detecting temporary change in $BL(1,1,1,1)$ processes. It is done with respect to the sample size, the type of outlier and the size of the coefficients of the $BL(1,1,1,1)$ process. The results show that, in general, the outlier detection procedure is capable of detecting TC, although the performance is affected if is large.

On a stochastic robust control. **Mamoud El-Borai** (Alexandria University, Egypt) IC/CT46/034

We consider some stochastic dynamical systems,which represents robustness that arise in controller and filter designs and also represent a remote control system in the presence of a network cable. The flexible arms connected by elastic joints of the robot is also studied. In addition we introduce a theory about the artificial intelligence. Some deterministic fractional dynamical systems is studied. These systems have many applications in robot and industry.

Keywords: Stochastic dynamical systems,stochastic robust control,flexible arms, artificial intelligence.

Nonlinearity management in optics. **Mason Porter** (Oxford Univ. UK & Caltech, USA) IC/CT4366/033

We present experimental, computational, and theoretical results concerning pulse stabilization and modulational instabilities in nonlinear optics by implementing "nonlinearity management" using layered Kerr media. The theoretical framework describing this system is a nonlinear Schrödinger (NLS) equation with a piecewise constant nonlinearity coefficient.

Asymptotics for some vibro-impact problems with a linear dissipation term. **Laetitia Paoli** (Université Saint-Etienne, France), Alexandre Cabot (Université de Limoges, France) IC/CT3926/033

Given $\gamma \geq 0$, let us consider the following differential inclusion

$$(S) \qquad \ddot{x}(t) + \gamma \dot{x}(t) + \partial\Phi(x(t)) \ni 0, \qquad t \in \mathbb{R}_+,$$

where $\Phi : \mathbb{R}^d \to \mathbb{R} \cup \{+\infty\}$ is a lower semicontinuous convex function such that int(dom Φ) $\neq \emptyset$. The operator $\partial\Phi$ denotes the subdifferential of Φ. When $\Phi = f + \delta_K$ with $f : \mathbb{R}^d \to \mathbb{R}$ a smooth convex function and $K \subset \mathbb{R}^d$ a closed convex set, inclusion (S) describes the motion of a discrete mechanical system subjected to the perfect unilateral constraint $x(t) \in K$ and submitted to the conservative force $-\nabla f(x)$ and the viscous friction force $-\gamma \dot{x}$. We define the notion of *dissipative* solution to (S) and we prove the existence of such solutions with conservation (resp. loss) of energy at impacts. If $\gamma > 0$ and $\Phi_{|\mathrm{dom}\Phi}$ is locally Lipschitz continuous, any dissipative solution to (S) converges, as $t \to +\infty$, to a minimum point of Φ. When Φ is strongly convex, the speed of convergence is exponential. Assuming as above that $\Phi = f + \delta_K$, suppose that the boundary of K is smooth enough and that the normal component of the velocity is reversed and multiplied by a restitution coefficient $r \in [0,1]$ while the tangential component is conserved whenever $x(t) \in \mathrm{bd}(K)$. We prove that any dissipative solution to (S) satisfying the previous impact law with $r < 1$ is contained in the boundary of K after a finite time. The case $r = 1$ is also addressed and leads to a qualitatively different behavior.

Dynamics in Bose–Einstein condensates. **Shu-Ming Chang** (National Tsing Hua University, Taiwan) IC/CT1385/033

We derive the asymptotic motion equations of vortices for the time-dependent Gross-Pitaevskii equation with a harmonic trap potential. The asymptotic motion equations form a system of ordinary differential equations which can be regarded as a perturbation of the standard Kirchhoff problem. From the numerical simulation on the asymptotic motion equations, we observe that the bounded and collisionless trajectories of three vortices form chaotic, quasi 2- or quasi 3-periodic orbits. Furthermore, a new phenomenon of $1:1$-topological synchronization is observed in the chaotic trajectories of two vortices. On the other hand, we study the distribution of m segregated nodal domains of the m-mixture of Bose-Einstein condensates under positive and large repulsive scattering lengths. It is shown that components of positive bound states may repel each other and form segregated nodal domains as the repulsive scattering lengths go to infinity. Efficient numerical schemes are created to confirm our theoretical results and discover a new phenomenon called verticillate multiplying, that is, the generation of multiple verticillate structures. In addition, our proposed Gauss-Seidel-type iteration method is very effective in that it converges linearly in 10 to 20 steps.

Mathematical modeling of rhythmic and pulsatile GnRH hormone secretion by synchronized GnRH neurons based on a robust mechanism. **Anmar Khadra** (University of British Columbia, Canada), Yuexian Li (University of British Colombia, Canada) IC/CT4352/036

Gonadotropin Releasing hormone (GnRH) secreted by GnRH neurons plays an essential role in the onset and progression of reproductive maturation, and regulation of hormonal changes that occur during menstrual and estrous cycle. There is a strong evidence suggesting that these GnRH neurons are capable of generating pulsatile and episodic neurosecretion of this hormone intrinsically. However, the underlying mechanism for the GnRH-pulse generator remains largely unknown. The presence of GnRH receptors on these neurons allow GnRH hormone to exert autocrine regulation on its own release. This led a group of experimentalist at NIH to propose in 2003 a mechanism describing this effect. We later developed in 2006 a mathematical model based on this proposed mechanism. The model was further extended to study synchrony in GnRH neurons by incorporating the idea of a common pool of GnRH hormone.

We shall present in this talk the mathematical model and few important aspects of it. We shall show that a heterogeneous family of coupled GnRH neurons is capable of secreting the hormone synchronously. In fact, we show that only 50neurons need to be active for pulse generation. The effects of averaging in the parameter-values, as well as the volume of the extracellular medium will be also discussed. In addition, several model predictions explaining the type of behaviour observed experimentally upon the injection of GnRH-agonist will be stated. These results will demonstrate the robustness of this process.

Weight-function for a crack in an orthotropic medium under impact-shear loading. **Subir Das** (B.P. Poddar Institute, India) IC/CT4176/009

The paper deals with the investigation of elastodynamic response of an infinite orthotropic medium containing a central crack under impact shear loading. Laplace and Fourier integral transforms are employed to reduce the dimensional wave propagation problem to the solution of a pair of dual integral equations in the Laplace transformed plane. These integral equations are then reduced to integral differential equations which have been solved in the low frequency domain by method of iteration. To determine time dependence, these equations are inverted to yield the dynamic stress intensity factor (SIF) for shear point force loading. These results have been used to obtain the SIF at the crack tip which corresponds to the weight function for the crack under shear loading. Analytical expressions of the weight function is used to derive SIF for polynomial loading.

Interfacial Griffith cracks between bonded dissimilar media. **Sudipta Chakraborty** (B.P.Poddar Institute, India) IC/CT4580/094

The paper deals with the interaction of a pair of outer cracks on a central crack situated at the interface of two dissimilar orthotropic half planes. The mixed boundary value problem is reduced to solving a pair of simultaneous singular integral equations which have finally been solved numerically by using Jacobi polynomials. The analytical expressions for stress intensity factors at the central crack tip and the expression of the strain energy release rate have been derived for general loading. Numerical values of the interaction effects of the outer cracks on the central crack have been calculated through stress magnification factors. It is seen that the interaction effects are either shielding or amplification depending on the size of the outer cracks and their spacing from the central crack.

Organiser: Changpin Li (Shanghai University, PR China)

Nonlinear time-series modelling and prediction using correlation analysis. **Andrzej Dydynski** (Politechnika Warszawska, Poland), Jarosław Arabas (Politechnika Warszawska, Poland) IC/CT3038/032

We present a novel way for time series prediction. The method is based on the correlation analysis and allows for handling nonlinearities of different type and character. The presented approach results in an approximation model that combines nonlinear units taken from radial basis functions (RBF) and from multilayer perceptrons (MLP). The approach leads to a low mean error of the approximation with a number of parameters significantly smaller when compared to RBF and MLP.

The main problem in the system identification is to find a good model structure. Many widely used nonlinear approximators (e.g., MLP or RBF) are linear combinations of nonlinear functions, called *base functions*. A larger model which contains more parameters is more likely to adapt to any nonlinear function but at the same time it is more likely to overfit. Here we present an Incrementally Built Heterogenous Model (IBHM) for modeling nonlinear systems by regression. The approach combines elements of several models in a single model structure.

The model is a weighted sum of base function and is incrementally expanded by adding one of many possible candidate base functions. The candidate base functions are inspired by artificial neurons from MLP and RBF. In each iteration of the IBHM method, a residue function being the difference between the approximated function values and the model output is computed. Then each candidate base function is scored according to the degree in which it resembles the residue function; a correlation measure is used for that purpose. The highest score candidate is included as a base function to the model, and the weight values assigned to base functions are recomputed. The process is repeated until a certain stop criterion is attained.

The idea of incremental model building has been raised by several authors, but usually it was constrained to homogenous models only, that is to models which used similar functional form of base functions. Probably the best known methods are Group Method of Data Handling (GMDH, originally used for polynomial models and then for MLP) [9] and Cascade Correlation method for MLP [8]. Moreover, in contrary to our approach, where the base function is selected basing on the residue function only, the aforementioned methods usually expand the model by a base function and then tune its parameters and weights.

In this paper we introduce the IBHM method and illustrate its properties using the benchmark data for time series prediction.

Two-state model of excitable system with time delayed feedback: renewal theory approach. **Andrey Pototsky** (Loughborough University, UK), Natalia Janson (Loughborough University, UK) IC/CT4562/031

We present a two-state model of an excitable system with time delayed feedback control. The two-state stochastic process can be interpreted as a renewal process with history-dependent residence time distributions (RTDs). The equilibrium RTDs in the sense of the averaging over all possible histories are introduced. Assuming that the transition rates are known functions of the history we derive an equation for the equilibrium RTDs for arbitrary delay time. We analytically solve this equation for moderate delay times in the case when the duration of the excited state is not affected by the noise. Analytic results are compared with numerical simulations of a bistable system with two time delays. Using the combination of the renewal theory power spectrum and the derived analytic expression for the equilibrium RTD, the piece-wise linear dependence of the main period of the noise-induced oscillations on the delay time is demonstrated. Delay-induced onset and enhancement of the coherence resonance is shown for positive feedback strength.

Stability analysis for nonlinear fractional differential systems. **Changpin Li** (Shanghai University, PR China) IC/CT467/038

In 1695, Leibniz wrote a letter to L'Hôpital and discussed whether or not the meaning of derivatives with integer orders could be generalized to derivatives with non-integer orders. L'Hôpital was somewhat curious about the problem and asked a simple question in reply: ŞWhat if the order will be 1/2?Ť. Leibniz in a re-reply letter dated September 30 of the same year, anticipated: ŞIt will lead to a paradox, from which one day useful consequences will be drawn.Ť The date September 30, 1695, is regarded as the exact birthday of the fractional calculus. In the following centuries, the theories of fractional calculus (fractional derivatives and integrals) underwent a significant and even heated development, primarily contributed by pure, not applied, mathematicians. The question put forward by Leibniz for a fractional derivative was an ongoing topic for more than 300 years. Many noted mathematicians contributed to this theory over the years, among them Liouville, Riemann, Weyl, Fourier, Abel, Lacroix, Leibniz, Grünwald and Letnikov. Only in the last few decades, however, did applied scientists and engineers realize that such fractional differential equations provided a natural framework for the discussion of various kinds of questions modelled by fractional equations, such as viscoelastic systems, electrode-electrolyte polarization, colored noise, dielectric polarization, boundary layer effects in ducts, electromagnetic waves, quantitative finance, quantum evolution of complex systems, and fractional kinetics, etc. In this paper, we focus on studying fractional differential systems, where the fractional derivatives means the Caputo derivatives. Here we mainly prove local asymptotical stability of trivial solutions to the nonlinear fractional differential systems.

Time-step volume-preserving control of dissipative systems. **Jose-Manuel Zaldivar Comenges** (Joint Research Centre, Italy), Fernanda Strozzi (Università Carlo Cattaneo, Italy) IC/CT43/015

We present a general control and optimization strategy based on time-step state space volume preservation. This is performed by maintaining the divergence of the system close to zero. The on-line implementation is shown for batch and semibatch chemical reactors. The divergence of these reactors is reconstructed on-line using only reactor temperature measurements by applying state space reconstruction techniques. The simulated results for batch and semibatch processes are compared with a traditional control scheme. This approach allows, in addition to the process control, the optimization from performance and safety points of view.

On the Lyapunov-exponent spectrum. **Vladimir Dobrynskii** (National Academy of Sciences of Ukraine, Kyiv) IC/CT434/015

A fixed (periodic) point of map is asymptotic stable iff all its the Lyapunov exponents evaluated at the given point are negative. Transition of one the exponents through zero generates a bifurcation of phase pattern in the given point neighbourhood. There is a conjecture that an asymptotic stability and bifurcation of non-trivial topologically transitive subsets of map are connected with negativity of the Lyapunov exponents evaluated at all the subset points. The latter is a reason to study the Lyapunov exponent spectrum. We have the following rigorous mathematical results: (1) the most of piecewise lenear maps have continuous the Lyapunov exponent spectrum; (2) that of the logistic map is countable at the least.

IC/CTS4676/03: Simulation of biological systems.

Stability techniques in SIR epidemic models. **Zaman Khan** (Pusan National University Korea, Sud-Korea) IC/CT4322/003

The SIR models underestimates the variation in diseases spread, especially, if there is a lag between the infection of an animal and its own release of infectious material. Several strategies have been used to studied the SIR epidemic models. In this paper, we consider a nonlinear SIR model. The nonlinear system describing the dynamics of the interaction between susceptible and infected in population. We would like to analyze the dynamical behavior of nonlinear system and approach the system by stability techniques, to find the equilibrium positions of the susceptible population. We presented some mathematical models and discussed quantitatively to illustrate the solution of infected population.

Key words: Stability techniques, SIR model, Population

Global-attractivity conditions for single-species models. **Viktor Tkachenko** (National Academy of Sciences of Ukraine, Kyiv) IC/CT833/036

We consider the nonlinear difference equation with delay which arises in many contexts in mathematical biology

$$x_{n+1} = qx_n + f_n(x_n, ..., x_{n-k}), \quad n \in \mathbf{Z}, \qquad (1)$$

where $q \in (0,1]$ and functions $f_n : \mathbf{R^{n+1}} \to \mathbf{R}$ are estimated by a rational function $r(x) = ax/(1+bx)$, with $a < 0, b \geq 0$, such that $r(\mathcal{M}(\mathbf{z})) \leq f_n(\mathbf{z}) \leq r(-\mathcal{M}(-\mathbf{z}))$, where $\mathcal{M}(\mathbf{z}) = \max_i\{0, z_i\}$, the first inequality holds for all $\mathbf{z} \in \mathbf{R^{k+1}}$, and the second one for all $\mathbf{z} \in \mathbf{R^{k+1}}$ such that $\min_i z_i > -1/b$.

Treating eq. (1) as retarded differential equation with piecewise constant delays and applying our result for functional-differential equations we obtain

Theorem 1. If $q \in (0,1)$, $b \neq 0$ and the condition

$$q^{k+1} > -\frac{a}{1-q} \ln \frac{a^2 - a(1-q)}{a^2 + (1-q)^2},$$

holds, then $\lim_{n\to\infty} x_n = 0$ for every solution $\{x_n\}$ of Eq. (1).

In contrast to functional-differential equations this condition is not sharp within the class of difference equations (1).

Theorem 2. For every positive integer k there exists $q_k \in (0,1)$ such that for $q \in (0, q_k]$ the inequality

$$\frac{a}{1-q} \geq -\frac{1+q^{k+1}}{1-q^{k+1}} \qquad (2)$$

assures the global attractivity of eq. (1). Condition (2) is sharp within the class of described above eqs. (1) with $q \in (0, q_k]$.

We apply our results to discrete versions of NicholsonŠs blowflies equation, the Mackey-Glass equations, and the Wazewska and Lasota equation.

We give conditions for global attractivity of eq. (1) in the case $q = 1$ and show that these conditions are sharp if the equation is strongly non-autonomous. As application, we consider Ricker's equation with delayed-density dependence and generalization of the Pielou equation.

This is a joint work with Prof. Sergei Trofimchuk.

Mechanisms for oscillations in a biological competition model. **Rodica Curtu** (Transilvania University of Brasov, Romania) IC/CT839/033

In our work we analytically investigate a four-dimensional nonlinear dynamical system that models perceptual bistability in the brain. Perceptual bistability is a phenomenon reported in experiments when a subject is presented with ambiguous (visual) stimuli: for example, the subject's eyes are forced to 'see' two distinct images; as a result, the brain cannot deal with two percepts in the same place in space and at the same time, and an alternation between these occurs.

Two variables in the model correspond to the activity of each of the two competing units and they evolve in fast time; other two variables are slow and are associated with a negative feedback received by each unit separately. The main parameter took into consideration is the external input strength I.

We prove analytically that oscillations in the system appear through a supercritical Hopf bifurcation when the parameter I is decreased from large to moderate value. At lower values of I another Hopf bifurcation takes place and the limit cycle dissapears. Both normal form and bifurcation diagrams are constructed.

In addition, due to the presence of the two time-scales, in the range of I where oscillations exist, the limit cycle formed through the Hopf bifurcation tends rapidly to a relaxation-oscillator. We also characterize the system's behavior in this regime, giving a theoretical interpretation of what is observed in experiments.

Binomial τ-leap spatial stochastic simulation algorithm. **Tatiana Marquez Lago** (University of Queensland, Australia), Kevin Burrage (University of Queensland, Australia) IC/CT518/012

In cell biology, cell-signaling pathway problems are often tackled with deterministic temporal models, well-mixed stochastic simulators and/or hybrid methods. But in fact, 3D stochastic spatial modeling of reactions happening inside the cell is needed in order to fully understand these cell signaling pathways. This is because noise effects, low molecular concentrations and spatial heterogeneity can all affect the cellular dynamics. However, there are ways in which important effects can be accounted without going to the extent of using highly-resolved spatial simulators (such as single-particle software), hence reducing the overall computation time significantly.

We present a new coarse grained modified version of the Next Subvolume Method, that allows the user to consider both diffusion and reaction events in relatively long simulation time spans as compared with the original method and other commonly used fully stochastic computational methods. Benchmarking of the simulation algorithm was performed through comparison with the Next Subvolume Method and well mixed models (Matlab), as well as stochastic particle reaction and transport simulations (ChemCell, Sandia National Laboratories).

Additionally, we consider a bi-stable system and construct a model based on a set of chemical reactions in the EGFR pathway. We analyse and outline the advantages of our presented Binomial τ-leap spatial stochastic simulation algorithm (τ-SSSA), in terms of efficiency and accuracy, in scenarios of both molecular homogeneity and heterogeneity.

Chaos in digital spaces. **Vinod Kumar Padingare Pisharathu Balakrishnan** (Rajagiri School of Engineering and Tech., India) IC/CT3857/035

Chaos in general topological spaces is widely studied. But in digital spaces $\mathbb{Z}2n$, with the usual topology it can be further explained. In this paper, we discuss chaos in $\mathbb{Z}2n$. The code space is the set of all words with infinite length in two symbols 0 and 1. It is a cantor set, so a fractal. We will show that in every digital space there exist at least one continuous function which is chaotic.

Representation of preference orderings on L^p-spaces by integral functionals: myopia, continuity and TAS utility. **Nobusumi Sagara** (Hosei University, Japan) IC/CT2354/030

The purpose of this paper is to present an axiomatic approach in a continuous time framework for representing preference orderings on L^p-spaces in terms of integral functionals. We show that if preference orderings on L^p-spaces satisfy continuity, separability, sensitivity, substitutability, additivity and lower boundedness, then there exists a utility function representing the preference orderings such that the utility function is an integral functional with an upper semicontinuous integrand satisfying the growth condition. Moreover, if the preference orderings satisfy the continuity with respect to the weak topology of L^p-spaces, then the integrand is a concave integrand. As a result, time additive separable (TAS) utility functions with constant discount rates are obtained.

Existence of solutions for an eigenvalue problem. **Najib Tsouli** (Université Mohammed Premier Oujda, Morocco), Siham El Habib (University Mohamed I, faculty of sciences, Oujda, Morocco), Abdelrachid El Amrouss (Université Mohammed Premier Oujda, Morocco) IC/CT836/033

In this work we study the existence of solutions for the eigenvalue problem $\Delta_p^2 u = \lambda m(x)|u|^{p-2}u$, $u \in W^{2,p}(\Omega)$ in a bounded smooth domain Ω, with Neumann boundary condition $\frac{\partial u}{\partial \nu} = 0$ on $\partial\Omega$, and where $m \in L^r(\Omega)$, $m \neq 0$ is a weight function which can change its sign, with $r = r(N,p)$ satisfying the conditions: $r > N/2p$ for $N/p \geq 2$ and $r = 1$ for $N/p < 2$.

Some geometric properties of a Banach sequence space $m(\phi,p)$ related to l_p. **Mohammed Mursaleen** (Aligarh Muslim University, India) IC/CT2606/034

Let C denote the space whose elements are finite sets of distinct positive integers. Given any element σ of C, we denote by $c(\sigma)$ the sequence $\{c_n(\sigma)\}$ which is such that $c_n(\sigma) = 1$ if $n \in \sigma$,and $c_n(\sigma) = 0$ otherwise. Further

$$C_s = \Big\{\sigma \in C : \sum_{n=1}^{\infty} c_n(\sigma) \leq s\Big\},$$

the set of those σ whose support has cardinality at most s, and

$$\Phi = \Big\{\phi = \{\phi_n\} \in \ell^0 : \phi_1 > 0, \Delta\phi_k \geq 0 \text{ and } \Delta\Big(\frac{\phi_k}{k}\Big) \leq 0 \text{ for } (k = 1,2,\ldots)\Big\},$$

where $\Delta\phi_n = \phi_n - \phi_{n-1}$.
For $\phi \in \Phi$, we define the following sequence space, introduced by W.L.C. Sargent[1].

$$m(\phi) = \Big\{x = \{x_n\} \in \ell^0 : \sup_{s\geq 1} \sup_{\sigma\in C_s} \Big(\frac{1}{\phi_s} \sum_{n\in\sigma} |\, x_n \,|\Big) < \infty\Big\}.$$

It is easy to see that the space $m(\phi)$ is a Köthe sequence space, indeed a BK-space with respect to its natural norm.

In[2] Malkowsky and Mursaleen have characterized the matrix classes $(X, m(\phi))$ for any FK-space X. Recently some of the geometric properties of $m(\phi)$ have been investigated[3]. In this paper we extend the space $m(\phi)$ to $m(\phi,p)$ as follows and study its relations with the classical sequence space l_p and some of its geometric properties (e.g., ordered continuity, Fauto's property, Banach–Saks property, fixed-point property, Schur property etc.).

$$m(\phi,p) := \Big\{x = \{x_n\} \in \ell^0 : \sup_{s\geq 1} \sup_{\sigma\in C_s} \frac{1}{\phi_s} \sum_{n\in\sigma} |x_n|^p < \infty\Big\}.$$

Periodic orbits in billiard systems. **Vadim Zharnitsky** (Univ. of Illinois at Urbana-Champaign, USA) IC/CT2846/030

The study of large sets (having positive measure) of periodic orbits in Birkhoff billiards is a classical problem in Hamiltonian dynamics. This problem is also important for the spectral asymptotics of the corresponding quantum mechanical system. It has been known that 2 and 3 period orbits constitute the set of zero measure in a Birkhoff billiard. We will describe a recently developed new approach to this problem relying on exterior differential systems and we will prove that the set of 4-period orbits in the smooth convex outer billiard (dual analog of Birkhoff billiard) has an empty interior.

On the Lagrangian formulation of a Lane–Emden-type equation and double reduction. **Chaudry Khalique** (North West University, South Africa) IC/CT4398/033

We classify the Noether point symmetries of the Lane–Emden-type equation $xy'' + ny' + x^\nu f(y) = 0$, for $\nu \neq 1$ with respect to the standard Lagrangian $L = \frac{1}{2}x^n y'^2 - x^{\nu+n-1}\int f(y)\,dy$ for various functions $f(y)$. We then obtain first integrals of the various cases which admit Noether point symmetry. Moreover, we find reduction to quadratures for the cases that admit Noether symmetries. Eight cases arise for the function $f(y)$ out of which seven cases result in Noether point symmetries.

Generalized de Rham–Hodge complexes, the related characteristic Chern classes and some applications to integrable multi-dimensional differential systems on Riemannian manifolds. **Anatoliy Prykarpatsky** (WMS AGH/IAPMM, Poland), Nikolay Bogolubov (jr.) (MI Russian Academy of Science) IC/CT936/034

The differential-geometric aspects of generalized de Rham–Hodge complexes naturally related with integrable multi-dimensional differential systems of M. Gromov type, as well as the geometric structure of Chern characteristic classes are studied. Special differential invariants of the Chern type are constructed, their importance for the integrability of multi-dimensional nonlinear differential systems on Riemannian manifolds is discussed. An example of the three-dimensional Davey–Stewartson type nonlinear strongly integrable differential system is considered, its Cartan type connection mapping and related Chern type differential invariants are analyzed.

Predictive differential equations. **Toru Ohira** (Sony CSL, Tokyo, Japan) IC/CT1875/015

We study a system whose dynamics are governed by predictions of its future states. In particular, the following type of equations are discussed,

$$\frac{dx(t)}{dt} = -\alpha x(t) + f(\bar{x}(\bar{t})), \quad \bar{x}(\bar{t} = t + \eta) = \eta \frac{dx(t)}{dt} + x(t),$$

with constants $\alpha > 0$, and a parameter $\eta > 0$, called *advance*. As shown here, we assume that the current rate of change of x continues for the duration of the advance to estimate the future state of x. This is a common prediction scheme for population projections, the national debt estimations and so on, and termed as *fixed rate prediction*.

We find that the increasing value of η, indicating how far ahead in time to make a prediction, can induce rather complex behaviors to otherwise simple dynamics with a stable fixed point when $\eta = 0$. This characteristics is similar to those found with delay differential equations with increasing delay. Hence, we discuss the comparison of this type of equations with delay differential equations, both of them are incorporating non-locality on the time axis.

We also report that an added noise can induce a behavior similar to *stochastic resonance* with a tuned combination of the noise strength and advance. We refer to this effect as *predictive stochastic resonance*.

4D rigid body and some cases of integrability. **Maxim Shamolin** (Moscow State University, Russian Federation) IC/CT3863/033

A mathematical model is constructed describing the deceleration of a solid 2D-, 3D- and 4D-body moving in a medium with a jet flow around the body in fore-dimensional space. The regime of translational deceleration is shown to be normally unstable. This has made it possible to develop a relatively simple technique for determining model parameters experimentally. An example of the application of this technique to a cylindrical body is presented.

The deceleration problem turned out to be more convenient for checking the build-up effect by experiment. The present study made it possible to develop a fairly simple and efficient technique for determining the unknown parameters of the model. Statement of a problem about the motion of a rigid body in a resisting medium when all the conditions of jet or separated flow are satisfied is given. This interaction of a medium with a body is concentrated on that part surfaces of a body, which has the form of a flat 1D- (cut), 2D- (circle) and 3D-disk.

At formation of dynamic model of influence of a medium on a 2D-, 3D- and 4D-body some properties of a medium are marked and its have connected in a serie of hypothesises. And the basic hypothesis is a hypothesis of quasistationarity. In this connection complete dynamic system describing investigated model is shown. Such class of motions which allow some constrain is considered. That constrain is allowing to consider some quantity as a constant in all time of a motion. That quantity is size of velocity of some characteristic point of a rigid body. The qualitative analysis of dynamic system obtained in space of quasivelocities is presented and it is recognized all the non-linear non-trivial properties.

Effective matrix formalism for singularity analysis of differential equations and new intergrable system in nonlinear elasticity. **Lydia Novozhilova** (Western Connecticut State University, USA), Sergei Urazhdin (West Virginia University, USA) IC/CT2702/030

New matrix formalism for finding series solutions to differential equations, developed by the authors earlier, and its extension to singularity analysis of ODEs and PDEs is presented.

Representing a power series as a product of two vectors

$$[a_0, a_1, a_2, \ldots] \cdot [1, x, /1!, x^2/2!, x^3/3!, \ldots]^T \qquad (1)$$

translates operations with analytic functions (like differentiation, multiplication by the independent variable, product of two such functions) into simple algebraic operations on the coefficient vectors and makes implementation of a classic power series method, even in the case of linear equations, elegant and simple. Using (1), a special matrix for computing the coefficient vector of the composite of two analytic functions can be defined, and information about the structure of this matrix can be pre-computed, stored, and used when needed. Using this universal matrix, nonlinear equations can be solved by

the power series method in the same simple and transparent manner as in the linear case. The extension of this formalism to the singularity analysis for differential equations with nonlinearity term given by analytic function is presented. The advantages of the approach are demonstrated on test problems (Burger's, KdV, Henon-Heiles equations). An example of new integrable system in nonlinear elasticity found by this method is also given.

IC/CTS4681/03: Bifurcation.

Organiser: Jan Sieber (University of Aberdeen, UK)

On the bandcount adding *bifurcation scenario.* **Viktor Avrutin** (Universität Stuttgart, Germany), Michael Schanz (Universität Stuttgart, Germany) IC/CT2416/035

An aperiodic and especially a chaotic attractor may consist of some number $K \geq 1$ of bands (also denoted as connected components). Multi-band chaotic attractors (MBCAs) defined by the bandcount $K > 1$, represent a well-known phenomenon on the field of nonlinear dynamics and are often involved in several bifurcations. It is for instance well-known, that the period doubling cascade is typically followed by an inverse band merging cascade, which represents a sequence of MBCAs with $p_0 \cdot 2^n$ bands, whereby n decreases from infinity to zero. We report a novel bifurcation scenario (bandcount adding scenario), which involves an infinite number of MBCAs organized not sequentially, but according to an infinite adding scheme. This adding scheme which is similar to the well-known Farey-trees, implies that between two MBCAs with bandcounts K_1 and K_2 there is an MBCA with $K_1 + K_2 - K^0$ bands (with some constant offset K^0). This scenario continues ad infinitum and resembles the period adding scenario known from many applications, but in contrast to this is formed by chaotic and not by periodic attractors. We study this scenario using a discontinuous map, which is actually considered by many authors as some kind of normal form of the discrete-time representation of many non-smooth systems of practical interest in the neighborhood of the point of discontinuity. By investigation of the structure of the 2D parameter space, we find out, that the bandcount adding scenario is related with discontinuity-induced codimension-1 bifurcations of unstable periodic orbits and with some specific discontinuity-induced codimension-2 bifurcations. Consequently, we describe the self-similarity of the chaotic area in parameter space and show, that in this area there are much more non-robust chaotic attractors than typically assumed.

On some generic types of discontinuity induced codimension-3 bifurcations. **Michael Schanz** (Universität Stuttgart, Germany), Viktor Avrutin (Universität Stuttgart, Germany) IC/CT2450/015

In this work we consider two families of piecewise-linear maps with a discontinuity, which is motivated by modeling of several power electronic circuits (DC/DC converters, Sigma-Delta modulators) and which is already investigated by many authors. However, the focus of these works lie on the investigation of the dynamics by variation of one or at most two system parameters. In many of these publications a great variety of bifurcation phenomena is revealed but unfortunately, a profound explanation of the complicated and often self-similar bifurcation structures and the systematics behind is missing.

In contrast to that, we investigate the full 3D parameter space of these families of systems and detect a number of discontinuity induced codimension-3 bifurcations. Some of them belong to an already known generic type [1,2], while others represent some new types not investigated so far.

Unfolding these bifurcations we are able to explain the systematics for a large number of the above mentioned bifurcation phenomena. In particular, several bifurcation scenarios observed under variation of one or two parameters represent an intersection of the extended bifurcation structures induced by codimension-3 bifurcation with the corresponding 1D or 2D parameter subspace.

The codimension-3 bifurcations reported here are characterized by two manifolds in the 3D parameter space, a 1D and a 2D one. The 1D manifold represents a codimension-2 bifurcation curve, whereas in the 2D manifold an infinite number of codimension-2 bifurcation curves are located. At the codimension-3 bifurcation point all these curves intersect. The reported bifurcations serve as organizing centers of periodic and aperiodic dynamics in the overall parameter space.

Neimark–Sacker Hopf bifurcations and snap-back repellers for the modified Nicholson–Bailey model. **Chen-Chang Peng** (No.300 Syuefu Rd., Chiayi City 60004, Taiwan) IC/CT3427/036

In this talk, we study the modified Nicholson-Bailey model with one parameter.

$$(x, y) \longmapsto (xe^{[3(1-x)-\alpha y]}, x(1 - e^{-\alpha y}))$$

Based on the bifurcation diagram versus parameter $\alpha \in (3.2, 3.3)$, we realize that a Neimark-Sacker Hopf bifurcation takes place at $\alpha = \alpha^* \in (3.2, 3.3)$. We hence investigate a rigorous proof of the existence of the Neimark-Sacker Hopf bifurcation. For each $\alpha \in (4.3, 5.8)$ we present a computer-assisted method to prove rigorously that the existence of snapback repellers for this model and hence it has chaotic behavior for each $\alpha \in (4.3, 5.8)$.

Control-based bifurcation analysis. **Jan Sieber** (University of Aberdeen, UK), Yuliya Kyrychko (University of Bristol, UK) IC/CT3141/033

We introduce a method for tracking nonlinear oscillations and their bifurcations in nonlinear dynamical systems. Our method does not require a mathematical model of the dynamical system nor the ability to set its initial conditions. Instead it relies on feedback stabilizability, which makes the approach applicable in experiments. The main area of application for this method are stability tests in civil and mechanical engineering that couple mechanical experiments and computer simulations, so-called hybrid, or substructured, tests. We will demonstrate our method using a simple hybrid system, consisting of a periodically forced mass-spring-damper (which is simulated in the computer) and a pendulum (which is real, and coupled to the simulation via actuators). Proof-of-concept computer simulations, including adverse effects such as coupling delay and measurement inaccuracies, have been successful. The incorporation of control-based bifurcation analysis into the hybrid experiment itself is currently in preparation.

Period-doubling cascades and mode interactions in coupled systems. **Philip Aston** (University of Surrey, UK) IC/CT1427/034

Suppose that an iterated map exhibits a period-doubling cascade. If two such maps are coupled, then the synchronised state will exhibit the same period-doubling cascade but there is also the additional possibility of symmetry-breaking bifurcations to non-synchronised states. By introducing a second parameter, a symmetry-breaking bifurcation and a period-doubling bifurcation can be made to occur at the same point, resulting in a mode interaction.

As the second parameter is varied from the value at the mode interaction, a second symmetry-breaking bifurcation may occur from the period 2 solutions, which will then be involved in another mode interaction at the next period-doubling bifurcation point. In this way, a complete cascade of mode interactions can occur.

A local analysis of such a mode interaction is performed. The global consequences together with a classification of different cases are then considered. Renormalisation theory is used to determine the universal behaviour and parameter scalings of such a system.

This work is done in collaboration with Himat Mir.

Self-oscillations in a system of regulation with hysteresis in the source therm. **Arzigul Shayakhmetova** (MIRAS University, Kazakhstan) IC/CT4559/033

For the parabolic system of regulation of temperature the questions of existence and uniqueness of periodical solutions are considered. It is formulated conditions of existance such kind of solutions and found estimates for periods of the self-oscillations. Hysteresis condition is on a boundary. Regulation condition is a linear continuous non-negative functional in C[0,1] or in L2(0,1), such that in C[0,1] the temperature is regulated in a fixed point, in L2(0,1) is regulated at an average temperature. Considered system has two parameters - the temperature of switching on and the temperature of switching off, influenced by periods of self-oscillations.

Organiser: Eugene Starostin (University College London, UK)

Coupled-cell systems: a paradigm for developing advanced magnetic sensors. **Antonio Palacios** (San Diego State University, USA) IC/CT1770/033

A large class of dynamic sensors exhibit nonlinear input-output characteristics, often corresponding to a bistable potential energy function. Examples include: magnetic field sensors, e.g., fluxgate sensors, ferroelectric sensors, and mechanical sensors, e.g., acoustic transducers made with piezoelectric materials. Many of these sensors have assisted mankind in analyzing and controlling thousands of functions for many decades. Computer memory has increased over many years through the use of magnetic sensors embedded in storage devices. Airplanes fly with higher safety standards because of the high reliability of noncontact switching with magnetic sensors. As new technologies emerge, however, more powerful and more efficient sensors are required.

Using ideas and methods from nonlinear dynamics research (in particular bifurcation theory) in Engineering, Mathematics, and Physics, we present theoretical and experimental results which demonstrate that higher sensitivity, lower power-consumption, and reduced costs, can all be achieved through an integrative approach that combines a novel Intelligent Magnetic Sensor (IMS) network architecture with a new read-out technique, the Residence Time Detection (RTD). The IMS/RTD concept is device-independent, so that similar principles can be readily adapted to a wide variety of sensors. In this work, we will consider, in particular, fluxgate magnetometers, Superconducting Quantum Interference Devices, and electric-field sensors. The research work is part of an ongoing collaboration between the Nonlinear Dynamical System group at San Diego State University and the Applied Chaos and Dynamics program at the Space and Naval Warfare Center in San Diego.

The dynamics of wheel shimmy with delay and tyre relaxation length. **Gábor Orosz** (University of Exeter, UK), Dénes Takács (Budapest University of Technology and Economics, Hungary), Gabor Stepan (Budapest University of Technology and Economics, Hungary) IC/CT1798/033

Lateral vibrations of wheels, the so-called the shimmy motion, may appear on airplane landing gears and motorcycle wheels and also on wheels of semi-trailers or articulated buses presenting a safety hazard. The nonlinear dynamics of shimmy is studied when the vibrations are due to the elasticity of the tyre. We consider the case when the wheel is pulled by a caster with constant velocity. The lateral deformations of the tyre are modelled by a stretched string model: the tyre ground contact is considered as a contact line which becomes deformed due to the lateral displacement of the wheel. Furthermore, we assume that each contact point sticks to the ground that results in a non-holonomic constraint expressed by a first order partial differential equation (PDE). With the appropriate choice of the boundary conditions, the so-called relaxation length of the tyre is also taken into account among other conventional tyre parameters like the specific stiffness and damping. The equation of motion is an integro differential equation (IDE). Assuming travelling wave solutions of the deformation allows us to transform the (PDE-IDE) system into a delay differential equation (DDE) with distributed delay. Here, the delay is the time needed for the leading point of the contact line to travel backward (relative to the caster) to the considered contact point. The linear stability investigation of the DDE shows that the steady rolling motion may loose its stability via codimension-one or codimension-two Hopf bifurcations as the parameters (like the towing speed and the caster length) are varied. Consequently, self-excited periodic and quasi-periodic oscillations can appear. The stability chart in the plane of the above parameters is determined semi-analytically, and also checked experimentally. The results confirm the importance of the relaxation length parameter in the model. Our results may help designers to eliminate this unwanted phenomenon.

Coupling and noise-induced patterns on $O(2)$ symmetric domains. **Peter Blomgren** (San Diego State University, USA) IC/CT2791/033

We study the Kuramoto–Sivashinsky equation, an example of a temporally pattern-forming dynamical system with a two-dimensional circular domain. Numerical integration of the pure KS equation leads to predominantly static cellular patterns. The introduction of additive noise (modeling thermal fluctuations), or parametric noise (modeling fluctuations in the physical control parameters) greatly increases the propensity of dynamic cellular states, which seems to explain the generic behavior of related laboratory experiments. Further, coupling to the heat equation (modeling interaction with the combustion chamber), gives rise to additional dynamic patterns. We report on the numerical simulation and analysis of recently found dynamic patterns, including modulated rotations, hopping, and homoclinic intermittent states. Many of these states were previously only observed in physical experiments or, in some cases, predicted by bifurcation analysis.

Regularity and determining modes for partly-dissipative reaction–diffusion systems. **Zhoude Shao** (Millersville University, USA) IC/CT1468/033

We consider an abstract system of evolutionary equations of the form

$$\begin{cases} u' + Au = F(u,v) \\ v' + B(u)v = G(u,v) \end{cases} \quad (1)$$

on a Hilbert space $H_1 \times H_2$, where A is a linear unbounded positive self-adjoint operator with a compact resolvent on H_1 and $B(u)$ is a linear bounded positive operator on H_2. Assume that system (1) possesses a global attractor (or more generally, a compact invariant set). Sufficient conditions are given to guarantee the smoothness of solutions of (1) on the global attractor. Also derived are results related to determination of solutions of system (1) by finitely many determining modes, the eigenfunctions of the operator A. The results obtained represent generalizations of the corresponding results by Hale and Raugel (J. Math. Pures Appl. (9)82 (2003)). Applications of these abstract results are given to partly dissipative reaction diffusion systems and systems admitting invariant regions which include the FitzHugh-Nagumo equations and Hodgkin-Huxley equations as examples.

Motion of polygonal curves by crystalline curvature flow and its generalization. **Tetsuya Ishiwata** (Gifu University, Japan) IC/CT1636/033

We discuss a motion of polygonal curves in the plane by crystalline curvature flow $V_j = H_j$ and its generalization $V_j = g(\theta_j, H_j)$. Here V_j, θ_j and H_j denote a normal velocity, a normal angle and a crystalline curvature of j-th edge of solution polygon, respectively. We consider the solution curves in the special class of polygonal curves which is characterized by an interfacial energy density. We call this class *admissible class*. In this talk, we show that (i) the solution polygon belongs to the admissible class as long as the solution exists, (ii) a crystalline curvature of each edges becomes non-negative before the extinction time and (iii) the solution polygon becomes star-shaped before the extinction time under some assumptions.

The equilibrium shape of an elastic developable Möbius strip. **Eugene Starostin** (University College London, UK), Gert van der Heijden (University College London, UK) IC/CT2500/015

The Möbius strip, obtained by taking a rectangular strip of plastic or paper, twisting one end through 180°, and then joining the ends, is the canonical example of a one-sided surface. As simple experimentation shows, a physical Möbius strip, when left to itself, adopts a characteristic shape independent of the type of material (sufficiently stiff for gravity to be ignorable).

This shape is well described by a developable surface that minimises the deformation energy, which is entirely due to bending. We assume that the material obeys Hooke's linear law for bending, then the energy is proportional to the integral of the non-zero principal curvature squared over the surface of the strip, which is taken to be an isometric embedding of a rectangle into 3D space.

The problem of finding the equilibrium shape of narrow Möbius strip was first formulated by M. Sadowsky in 1930 who turned it into a 1D variational problem represented in a form that is invariant under Euclidean motions. Later W. Wunderlich generalised this formulation to a strip of finite width, but the problem has remained open although *geometrical* constructions of developable Möbius strips have appeared.

We apply an invariant geometrical approach based on the variational bicomplex formalism to derive the first equilibrium equations for a finite-width developable strip thereby giving the first non-trivial demonstration of the potential of this approach. The boundary-value problem for the Möbius strip offers a fitting example for application of these equations.

Numerical solutions for increasing width-to-length ratio show the formation of creases bounding nearly flat triangular regions, a feature also familiar from fabric draping and paper crumpling. This suggests that our approach could give new insight into energy localisation phenomena in unstretchable elastic sheets, which for instance could help to predict points of onset of tearing.

Exact controllability of semilinear thermoelastic system with control and non-linearity in thermal component only. **Nutan Tomar** (IIT Roorkee, India), Nagarajan Sukavanam (IIT Bombay, India) IC/CT3556/030

In this paper, we are concerned with the study of exact controllability of a semi-linear thermo-elastic system described by the partial differential equations:

$$\omega_{tt} - \gamma\Delta\omega_{tt} + \Delta^2\omega + \alpha\Delta\theta = 0 \text{ in } \Omega_T \quad (1a)$$

$$\theta_t - \Delta\theta + \sigma\theta - \alpha\Delta\omega_t + g(\omega) = u \text{ in } \Omega_T \quad (1b)$$

with Dirichlet boundary conditions and given initial conditions. Here Ω is a bounded open subset of R^2 with smooth boundary and $\Omega_T = \Omega \times (0,T)$, where $T > 0$ is the final time at which we want to achieve the controllability. The non-linearity is due to the non-linear function g, and u is the control function which acts only on the equation (1 b). The system (1) without the control and non-linear function g is a partial differential equation model which describes a Kirchhoff plate subjected to a thermal damping. Here ω is the displacement θ is the temperature of the plate and $\alpha > 0, \gamma \geq 0, \sigma \geq 0$ are the given system parameters.There is a vast amount of literature with various types of controllability of linear systems (i.e. $g = 0$) similar to (1) with the controls either as distributed controls or through the boundary. It has been proved in recent litrature that if the lipschitz constant of g is sufficiently small, then the semilinear system is exact controllable. In this paper, we removed the condition that lipschitz constant is sufficiently small for the exact controllability of system (1).
